Haploinsufficiency of *SF3B4*, a Component of the Pre-mRNA Spliceosomal Complex, Causes Nager Syndrome

Francois P. Bernier,[1,3,17,*] Oana Caluseriu,[1] Sarah Ng,[2] Jeremy Schwartzentruber,[4] Kati J. Buckingham,[5] A. Micheil Innes,[1,3] Ethylin Wang Jabs,[6] Jeffrey W. Innis,[7] Jane L. Nager syndrome, first described more than 60 years ago, is the archetype of a class of disorders called the acrofacial dysostoses, which are characterized by craniofacial and limb malformations. Despite intensive efforts, no gene for Nager syndrome has yet been identified. In an international collaboration, FORGE Canada and the National Institutes of Health Centers for Mendelian Genomics used exome sequencing as a discovery tool and found that mutations in *SF3B4*, a component of the U2 pre-mRNA spliceosomal complex, cause Nager syndrome. After Sanger sequencing of *SF3B4* in a validation cohort, 20 of 35 (57%) families affected by Nager syndrome had 1 of 18 different mutations, nearly all of which were frameshifts. These results suggest that most cases of Nager syndrome are caused by haploinsufficiency of *SF3B4*. Our findings add Nager syndrome to a growing list of disorders caused by mutations in genes that encode major components of the spliceosome and also highlight the synergistic potential of international collaboration when exome sequencing is applied in the search for genes responsible for rare Mendelian phenotypes.

Nager syndrome (MIM 154400), first described by Nager and De Reynier in 1948,[1] is the prototype for a group of disorders collectively referred to as the acrofacial dysostoses (AFDs), which are characterized by malformations of the craniofacial skeleton and the limbs (Figure 1).[2,3] The major facial features of Nager syndrome include downslanted palpebral fissures, midface retrusion, and micrognathia, the latter of which often requires the placement of a tracheostomy in early childhood. Limb defects typically involve the anterior (i.e., radial) elements of the upper limbs and manifest as small or absent thumbs, triphalangeal thumbs, radial hypoplasia or aplasia, and radioulnar synostosis. Phocomelia of the upper limbs and, occasionally, lower-limb defects have also been reported.[4] The presence of anterior upper-limb defects as opposed to posterior upper-limb defects and the typical lack of lower-limb involvement distinguishes Nager syndrome from Miller syndrome (MIM 263750), another rare AFD.[5] However, distinguishing Nager syndrome from other AFDs, including Miller syndrome, can be challenging, and there are numerous reports of individuals and families that have been difficult for researchers to categorize.

Nager syndrome is rare, and, to date, fewer than 100 cases have been reported.[6] Most cases are sporadic, but both autosomal-dominant[7–9] and autosomal-recessive[10,11] segregation have been reported. This has led to the widespread speculation that Nager syndrome is genetically heterogeneous. The rarity of this syndrome, which typically occurs as a simplex case, and the different modes of inheritance have made identification of the causal gene(s) intractable to conventional gene-discovery approaches. Given the phenotypic overlap between Nager and Miller syndromes and given our recent finding that Miller syndrome is caused by mutations in *DHODH* (MIM 126064),[12] we and others suspected that the disorders might be allelic or caused by genes in the pyrimidine biosynthetic pathway. However, screening of families affected by Nager syndrome ($n > 12$) did not reveal any mutations in these genes (Bamshad et al., unpublished data).

To identify a gene for Nager syndrome, investigators at the University of Calgary as part of the FORGE (Finding of Rare Disease Genes) Canada Consortium and investigators at the University of Washington (UW) as one of the National Institutes of Health Centers for Mendelian

Figure 1. Characteristic Craniofacial and Limb Malformation in Individuals with Nager Syndrome and *SF3B4* Mutations
Typical features of the face include downslanted palpepral fissures, malar flattening, and variable external ear malformations. Hand abnormalities include small thumbs and, in some cases, upper-limb reduction defects (C-1). Labels correspond to those in Tables 1–3, where a detailed description of each individual is provided.

Genomics independently performed exome sequencing.[13] Between both institutions, a total of 35 independent families (a total of 41 affected individuals) afflicted with Nager syndrome were available for study (Figure 1 and Tables 1–3). These families consisted of 28 simplex families, including one in which the parents were consanguineous, and seven multiplex families: two with mother-to-son transmissions, one with a father-to-daughter transmission, two with mother-to-daughter transmissions, one consisting of an affected mother and her two affected sons, and one with a pair of affected monozygotic twins (Table S1, available online). An experienced clinical geneticist was responsible for each diagnosis of Nager syndrome, each participant provided informed consent, and studies were approved by the institutional review boards of the University of Calgary, the University of Washington, and Seattle Children's Hospital.

Exome sequencing of five independent simplex cases was performed by the FORGE Canada team at the McGill University and Genome Québec Innovation Centre according to the manufacturer's (Illumina) standard protocols for the Agilent SureSelect 50 Mb exome enrichment kit, and captured targets were sequenced on a HiSeq2000 sequencer. Reads were aligned to a human reference (hg19) with the Burrows-Wheeler Aligner (BWA),[14] and indel realignment was performed with the GATK.[15] Duplicate reads were then marked with Picard and excluded from downstream analyses. Coverage of consensus coding sequence (CCDS) bases was assessed with GATK, which showed that all samples had >90% coverage of CCDS bases and a depth of at least 10×. For each sample, single-nucleotide variants (SNVs) and short insertions and deletions (indels) were called with the use of SAMtools pileup[16] with the extended base alignment quality (BAQ) adjustment (-E), and they were then quality filtered so that at least 20% of the reads supported the variant call. We annotated variants by using both Annovar[17] and custom scripts to identify whether they affected protein-coding sequence and whether they were previously observed in dbSNP132, 1000 Genomes Project data (Nov. 2011), or ~300 exomes previously obtained at the center.

At the University of Washington, exome sequencing was performed on four simplex cases with Nager syndrome and three unrelated individuals from multiplex families; these three latter individuals included one affected child born to an affected parent and two affected parents, each of whom had at least one affected child. In brief, we performed exome capture on a shotgun library created from 1 μg of genomic DNA by using the ~62 Mb target from Roche Nimblegen SeqCap EZ v2.0 (~300,000 exons and flanking sequence). Exome capture was followed by massively parallel sequencing on a HiSeq 2000 sequencer

(Illumina). BAM files were also aligned to a human reference (hg19) with the BWA,[14] and duplicate reads were removed with Picard. Variant detection and genotyping were performed with the UnifiedGenotyper tool from GATK (refv1.529). Exome completion was defined as having >90% of the exome target at >8× coverage. Typically, this requires that the target have a mean coverage of 60–80×. An automated pipeline, the SeattleSeq Annotation Server, was used for the annotation of variants. Novel variants are defined as those not observed in dbSNP version 134 or in 1,200 exomes drawn from a subset of samples from the National Heart, Lung, and Blood Institute (NHLBI) Exome Sequencing Project (ESP).

Because the mode of inheritance of Nager syndrome for most cases was unclear, discrete filtering for novel variants in the same gene shared among cases was performed under both autosomal-dominant and autosomal-recessive models. In neither cohort was a gene found to be shared among all the unrelated Nager-syndrome cases under a recessive mode of inheritance, i.e., those who were compound heterozygous for two novel variants or homozygous for a rare novel variant. This suggested that if Nager syndrome were an autosomal-recessive disorder, it would have high locus heterogeneity. Under an autosomal-dominant model, one gene, *TTN* (MIM 188840), in the FORGE cohort and two genes, *MUC12* (MIM 604609) and *MUC16*

(MIM 606154), in the UW cohort had novel variants shared among all unrelated cases. These large genes are frequent sources of false-positive calls and were excluded from consideration.

In both cohorts, several genes had novel or rare variants shared among two, three, or four cases with Nager syndrome, and prioritizing these candidates was not possible. We further filtered the gene list from the FORGE cohort by assigning higher priority to variants predicted to have a greater deleterious impact on protein function (i.e., nonsense, frameshift, initiation-codon, and splice-site variants) and then reanalyzed the list. A single gene, *SF3B4* (MIM 605593), which encodes a component of the U2SNP of the major spliceosome, was found to have different novel variants in two unrelated cases of Nager syndrome (Table S2). In the UW cohort, subsequent discrete filtering limited to only genes with novel variants shared among the three familial-Nager-syndrome cases identified three candidate genes, including *SF3B4*. In two of these cases, the variant identified (c.1A>G [p.M1?]) was identical to one of the *SF3B4* variants found in the FORGE cohort. Sanger sequencing subsequently

[a]Confirmed familial mutation.

confirmed that all four novel variants were present in *SF3B4* and that the variants were de novo in the FORGE simplex cases and inherited from an affected parent (one case) and transmitted to an affected child (one case) in the UW families.

Further evidence supporting the hypothesis that mutations in *SF3B4* cause Nager syndrome was provided by a recent finding that mutations in *EFTUD2* (MIM 603892), which also encodes a component of the spliceosome, cause a mandibulofacial dysostosis with microcephaly (MFDM [MIM 610536]) whose craniofacial findings overlap the symptoms of Nager syndrome.[18] Furthermore, an individual had previously been reported to have an unclassifiable AFD and a 1q21.2 deletion spanning the region containing *SF3B4*.[19] Collectively, these results strongly suggest that mutations in *SF3B4* cause Nager syndrome.

To determine the extent to which *SF3B4* mutations explain cases of Nager syndrome, we used Sanger sequencing to screen *SF3B4* in a validation cohort of 23 additional unrelated families affected by Nager syndrome. We also screened the eight individuals who underwent exome sequencing but in whom no *SF3B4* mutation was found. Collectively, between the initial study cohort and our validation studies, *SF3B4* mutations were found in 20 of the 35 (57%) families, including five of the seven families with more than one individual affected by Nager syndrome. For simplex cases, 15 of 28 (54%) had mutations in *SF3B4*, and in each of the five simplex cases for which DNA was available from both parents, the *SF3B4* mutation was confirmed to have arisen de novo. No *SF3B4* mutation was identified in the single consanguineous family in our cohort. Overall, 25 out of 41 (61%)

The following abbreviation is used: NA, parental DNAs were unavailable for the confirmation of inheritance.
[a]Mother's sample was not available for testing.

Nager-syndrome-affected individuals in our cohort had mutations in *SF3B4* (Tables 1–3 and Table S1).

A total of 18 unique mutations were identified, and these include 14 frameshift, two nonsense, one splicing, and one missense mutation (c.1A>G [p.Met1?]), the last of which is predicted to abolish the methionine initiation codon and was the only recurrent (i.e., in three unrelated families) mutation found (Table 4 and Figure 2). Four of the Nager-syndrome cases with a *SF3B4* variant that was missed by exome sequencing were found to have indels, and manual inspection of the BAM files revealed that they all occurred in regions with relatively low coverage (i.e., <8×). None of the *SF3B4* missense, nonsense, or splice-site mutations identified in the participants were found in >10,800 chromosomes sequenced as part of the NHLBI-ESP (see Web Resources). Indeed, only 22 rare (minor allele frequency of <0.5%) SNVs, six of which were missense variants, were observed in this ESP dataset. Accordingly, *SF3B4* is highly conserved, and most new mutations are likely to be selected against, consistent with the observation that most of the mutations we identified are de novo events.

All of the *SF3B4* variants identified are predicted to encode a truncated polypeptide chain or an elongated polypeptide with an altered 3′ end in the absence of nonsense-mediated RNA decay (Figure 2C). Together with the observation that a deletion of chromosomal region 1q12–q21.1 or q21.3, which encompasses *SF3B4*, has been reported in a child with characteristics of Nager syndrome,[19] our findings suggest that Nager syndrome probably results from haploinsufficiency of *SF3B4*.

SF3B4 encodes SAP49, a spliceosomal protein that is one of seven core proteins of the mammalian SF3B complex and is highly conserved with two RNA recognition motifs (RRMs) followed by a proline-glycine rich domain (Figure 2B). During assembly of the U2SNP prespliceosomal complex, SAP49 binds to the pre-mRNA just upstream of the branch point sequence but also interacts specifically with other U2 snRNPS, particularly SAP145, suggesting that SAP49 plays a crucial role in tethering the U2 snRNP to the branch site.[20]

Our discovery adds Nager syndrome to an emerging group of disorders caused by mutations in genes that encode subunits of the spliceosome. Mutations in splicing factors were initially reported in patients with autosomal-dominant retinitis pigmentosa.[21–24] Subsequently, biallelic mutations in *RNU4ATAC* (MIM 601428), a component of the minor spliceosome required for excision of the U12 class of introns, were reported to cause lethal microcephalic osteodysplastic primordial dwarfism type I (MIM 210710).[25,26] Most recently, mutations in *EFTUD2* have been reported in individuals with MFDM, a disorder with many features that overlap those of Nager syndrome.[18] Although the limbs are typically normal in MFDM, the

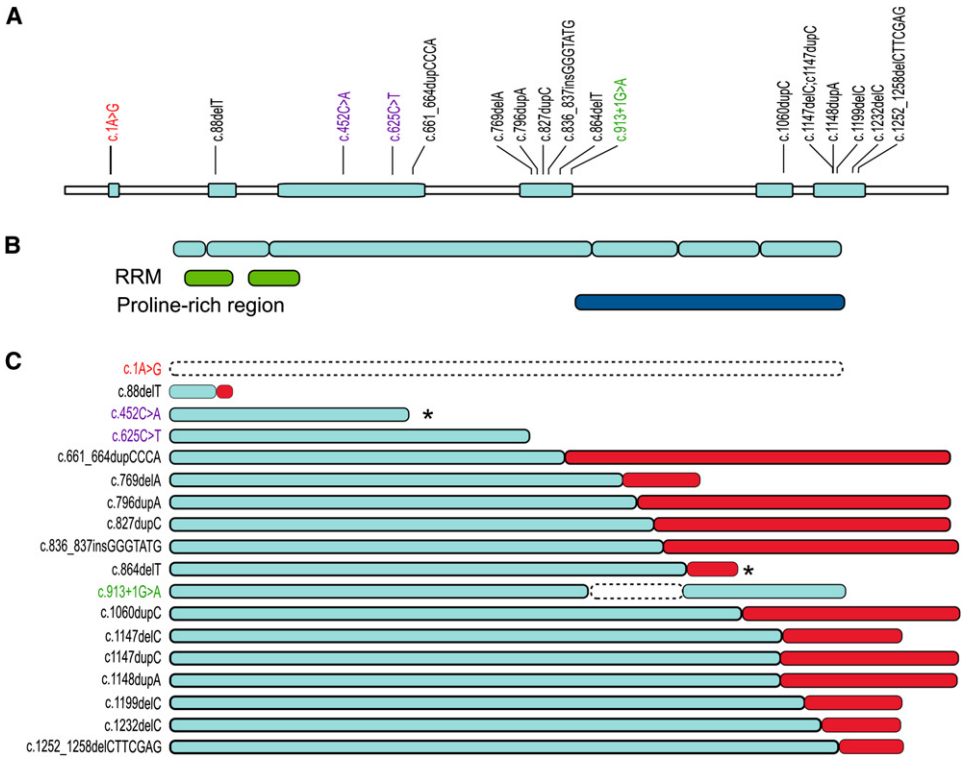

Figure 2. Location of *SF3B4* Mutations that Cause Nager Syndrome

(B) Domain structure of SAP49. The following abbreviation is used: RRM, RNA recognition motif.
(C) Predicted translational effect of each *SF3B4* mutation. Dotted lines indicate a deletion, the blue box indicates reference amino acid sequences, the red bar indicates altered amino acid sequences, and asterisks indicate potential for nonsense-mediated RNA decay.

fact that some individuals have thumb abnormalities suggests that Nager syndrome and MFDM could be confused with one another.[18] To this end, we screened *EFTUD2* in all of the UW cohort Nager-syndrome individuals who did not have mutations in *SF3B4*, and we identified a single individual with a novel nonsense mutation (c.2495C>G [p.Tyr832*]). This mutation affects the amino acid residue adjacent to an *EFTUD2* mutation (c.2493C>A [p.Tyr831*]) found in one family with MFDM.[18] In retrospect, this individual also had microcephaly, suggesting that MFDM rather than Nager syndrome is the appropriate diagnosis.

It is clear that SAP49 and U5-116KD, encoded by *EFTUD2*, are critical components of the major spliceosome, but their role in the pathogenesis of defects in craniofacial and limb development is unknown. The mouse homolog of *SF3B4*, SAP49 (mSAP49), is highly conserved and shows broad expression in adult tissues.[27,28] Whole-mount in situ hybridization shows high expression at day 11 after conception in limbs and somites, as well as dynamic patterns of expression in the developing heart.[27] These results suggest that mSAP49 expression during development varies in both a time- and tissue-specific manner. Whereas limb malformations are frequently seen in Nager syndrome, the fact that only 2 out of 20 (10%) *SF3B4*-mutation carriers had cardiac defects suggests that *SF3B4* haploinsufficiency has only minor effects on human heart development.

Spliceosomes are not only critical for mediating intron splicing but are also key regulators of alternative splicing[29,30] and, as such, play an important role in the control of gene-expression pathways. Furthermore, alternative splicing of mRNA is a major source of protein diversity, and tissue-specific alternative splicing further increases the diverse cellular functions of proteins. Spliceosomes might directly regulate developmental genes via the control of splicing or tissue specificity. Thus, the defects observed in individuals with Nager syndrome could be due to aberrant splicing of genes involved in craniofacial and limb development. However, this hypothesis is not supported by evidence from *sf3b1*$^{+/-}$-heterozygous-null mice. Isono et al.[31] reported that *Sf3b1*$^{+/-}$ heterozygous mice exhibited skeletal malformations concomitant with ectopic *Hox* expression. Because polycomb group (PcG) proteins are required for the stable repression of *Hox*, Isono et al. measured the transcript levels for five PcG genes and three Hox genes.[31] Despite *Sf3b1* expression levels that were reduced by half in the *sf3b1*$^{+/-}$ mice, transcript levels of the PcG and Hox genes were similar to those of the controls. Thus, the homeotic transformations in *sf3b1*$^{+/-}$ mice appear to be independent of alterations in overall gene transcription.

Further evidence that mutations in *SF3B4* might cause Nager syndrome via a mechanism unrelated to its role in mediating splicing is provided by studies linking SAP49 to bone morphogenetic protein (BMP) signaling. BMP proteins are multifunctional growth factors with roles in early embryogenesis and skeletogenesis. BMP2 and BMP4 are the main sources of BMP signaling in the developing limbs and also play a critical role in chondrogenesis.[32] To find molecules specific to BMP-mediated signal transduction, Watanabe et al.[33] identified SAP49 by using BMPR-IA, a BMP receptor, as a bait protein in a yeast two-hybrid screen. Coimmunoprecipitation and immunoblot analysis confirmed their interaction in mammalian cells.[33] SAP49 is also found in cell-membrane fractions, and overexpression of SAP49 inhibits BMP-2-mediated osteogenic and chondrocytic differentiation. These findings suggest that SAP49, in addition to its role in mRNA splicing, might also specifically inhibit BMP-mediated osteochondral cell differentiation[33]

In summary, we applied exome sequencing across 12 unrelated cases to discover that mutations in *SF3B4* cause Nager syndrome and explain ~60% of the cases in our overall cohort, including five out of seven multiplex families and 54% of simplex cases. The clinical characteristics of individuals with Nager syndrome caused by *SF3B4* mutations were indistinguishable from those without *SF3B4* mutations. Although partial or whole-gene deletions or mutations in noncoding regulatory regions of *SF3B4* might explain some of the *SF3B4* mutation-negative cases in our cohorts, this observation is strong evidence that Nager syndrome is genetically heterogeneous. Our findings also indicate that the phenotypic overlap between AFD Nager syndrome and MFDM is probably due in part to a shared defect in the same biological process and suggests that similar clinical phenotypes for which the cause has yet to be identified might be due to variants in genes that have a similar role.

Supplemental Data

Supplemental Data include two tables and supplemental acknowledgments and can be found with this article online at http://www.cell.com/AJHG.

Acknowledgments

We thank the families for their participation and the Foundation for Nager and Miller Syndromes for their support. Our work was supported in part by grants from the National Institutes of Health (NIH) National Human Genome Research Institute (1U54HG006493 to M.B., D.N., and J.S.; 1RC2HG005608 to M.B., D.N., and J.S.; and 5RO1HG004316 to H.T.), the Life Sciences Discovery Fund (2065508 and 0905001), the Washington Research Foundation, and the NIH National Institute of Child Health and Human Development (1R01HD048895 to M.B.). S.B.N. is supported by the Agency for Science Technology and Research, Singapore. The FORGE (Finding of Rare Disease Genes) Steering Committee includes Kym Boycott (leader; University of Ottawa), Jan Friedman (coleader; University of British Columbia), Jacques Michaud (coleader; Université de Montréal), Francois Bernier (University of Calgary), Michael Brudno (University of Toronto), Bridget Fernandez (Memorial University), Bartha Knoppers (McGill University), Mark Samuels (Université de Montréal), and Steve Scherer (University of Toronto). FORGE CANADA was funded by the Government of Canada through Genome Canada, the Canadian Institutes of Health Research (CIHR), and the Ontario Genomics Institute (OGI-049). Additional funding was provided by Genome Québec and Genome British Columbia. O.C. and H.R. are supported by the CIHR Training Program in Genetics, Child Development, and Health. G.A. is a Clinician Scientist of the CIHR and is supported by the Fondation Nussia et André Aisenstadt.
