Background: Exercise and diet control are fundamental approaches to metabolic conditions caused by high fat diet (HFD).

Results: HFD-induced memory deficit and A β deposition were more ameliorated in the exercise- than in the diet control-induced mice.

Conclusion: Exercise was more effective than diet control in preventing HFD-induced AD development.

Significance: Exercise has the highest priority in the prevention of AD.

Accumulating evidence suggests that some dietary patterns, specifically high fat diet (HFD), increase the risk of developing sporadic Alzheimer disease (AD). Thus, interventions targeting HFD-induced metabolic dysfunctions may be effective in preventing the development of AD. We previously demonstrated that amyloid precursor protein (APP)-overexpressing transgenic mice fed HFD showed worsening of cognitive function when compared with control APP mice on normal diet. Moreover, we reported that voluntary exercise ameliorates HFD-induced memory impairment and β -amyloid (A β) deposition. In the present study, we conducted diet control to ameliorate the metabolic abnormality caused by HFD on APP transgenic mice and compared the effect of diet control on cognitive function with that of voluntary exercise as well as that of combined (diet control plus exercise) treatment. Surprisingly, we found that exercise was more effective than diet control, although both exercise and diet control ameliorated HFD-induced memory deficit and A β deposition. The production of A β was not different between the exercise- and the diet control-treated mice. On the other hand, exercise specifically strengthened the activity of neprilysin, the A β -degrading enzyme, the level of which was significantly correlated with that of deposited A β in our mice. Notably, the effect of the combination treatment (exercise and diet control) on memory and amyloid pathology was not significantly different from that of exercise alone. These studies provide solid evidence that exercise is a useful intervention to rescue HFD-induced aggravation of cognitive decline in transgenic model mice of AD.

Alzheimer disease (AD),² the most common cause of dementia, is poised to be a significant public health crisis. The occurrence of AD is largely sporadic, typically affecting individuals aged over 65 years. Amyloid plaque is one of the pathological hallmarks of AD. Amyloid plaques are composed of β -amyloid (A β), which are derived from the amyloid precursor protein (APP) via proteolytic cleavages by β - and γ -secretases. A widely accepted hypothesis about AD pathogenesis is the amyloid cascade hypothesis in which A β plays a crucial role in neurodegeneration (1). Importantly, recent studies have implied that soluble A β oligomers may be the main culprit of AD pathogenesis (2–4).

High fat diet (HFD) is prevalent in modern society, and HFD-induced metabolic condition is becoming a worldwide issue because it leads to obesity, type 2 diabetes mellitus, and hypercholesterolemia. More importantly, accumulating evidence suggests that some dietary patterns, specifically HFD, increase the risk of developing sporadic AD (5). Experimental studies also support this idea. For example, application of HFD for APP transgenic mice exacerbated pathological alterations in the brain and their memory deficits (6, 7). In contrast, it is widely known that composite dietary patterns such as the Mediterranean diet, characterized by high intake of vegetables, unsaturated fatty acids, and wine, are related to lower risk for AD (8). These studies clearly indicate that there is an association between metabolic conditions and a higher risk of sporadic AD.

Exercise and diet control are fundamental approaches in the treatment of metabolic conditions. They might also become useful ways to prevent the development of AD. For example, a prospective study revealed that physical activity is protective against the development of cognitive impairment in AD and that the highest activity group showed a lowered incidence of AD (9). Recently, we also demonstrated that voluntary exercise

ameliorates HFD-induced memory deficit and A β deposition in APP transgenic mice (7), indicating that interventions to reduce metabolic conditions can become the preventive method for AD. However, it still remains unknown what kind of intervention targeting metabolic conditions is more effective.

In the present study, we used the AD model mice with metabolic conditions through HFD (APP-HFD mice), which we had previously established (7). In addition to voluntary exercise, we preventively conducted diet control or the combination of diet control with exercise using APP-HFD mice followed by comparing the effect of these interventions on cognitive function and amyloid pathology. Here, we show that diet control improved metabolic conditions including hyperinsulinemia and hypercholesterolemia of APP-HFD mice better than exercise. However, exercise more effectively ameliorated HFD-induced memory deficit and A β deposition than diet control (despite higher serum insulin/cholesterol levels). Exercise specifically enhanced the activity of neprilysin, which we speculate may be responsible for the reduction of the A β level. These results clearly indicated that exercise, affecting the process of A β degradation, could be a more effective way to ameliorate the AD progression caused by metabolic dysfunctions than diet control.

EXPERIMENTAL PROCEDURES

Animals and Dietary Conditions

Human APP transgenic mice overexpressing the familial AD-linked mutations bearing both Swedish (K670N/M671L) and Indiana (V717F) mutation (APP^{Swe/Ind}) (10), which have been imported from The Jackson Laboratory, were used in the present study. They were maintained as heterozygotes, and male and female mice were housed separately. Age- and sex-matched (1:1, male: female) mice were exposed to either a standard diet (10% fat, 70% carbohydrate, and 20% protein, Oriental Yeast Co., Ltd., Tokyo, Japan) or an established HFD (caloric composition, 60% fat, 20% carbohydrate, and 20% protein, Research Diet, Inc., New Brunswick, NJ) for 20 weeks, from 2–3 to 7–8 months of age. To examine the effect of voluntary exercise (Ex) on APP transgenic mice fed HFD (APP-HFD mice), the cage of the mice was changed to a 2.4 times larger one equipped with a running wheel as well as objects after 10 weeks of HFD (APP-HFD+Ex mice) (7). The mice spent 10 weeks in the exercise condition in the presence of HFD. To examine the effect of diet control (Dc) on APP-HFD mice, HFD was replaced with standard diet after 10 weeks of HFD and mice were fed with standard diet for another 10 weeks (APP-HFD+Dc mice). To examine the effect of the combinatory intervention of Ex and Dc, the mice spent 10 weeks in the exercise condition in the presence of standard diet after 10 weeks of HFD (APP-HFD+Ex+Dc mice). After the dietary manipulation, metabolic changes in these mice were analyzed followed by the assessment of memory function through the Morris water maze test, as described below. After the analysis of memory function, the brains were extracted and cut sagittally into left and right hemispheres. The left hemisphere was fixed in 4% paraformaldehyde for histological analysis. After removing the olfactory lobe and cerebellum, the right hemisphere was rapidly

frozen in liquid nitrogen for biochemical analysis. All animal experiments were performed in compliance with the Guidelines for the Care and Use of Laboratory Animals of the Kyoto University.

Assessment of Metabolic Changes

Blood glucose content was measured by using LabAssay glucose (Wako Pure Chemical Industries, Osaka, Japan). To assess glucose intolerance in these mice, we conducted the intraperitoneal glucose tolerance test. Mice were given a single dose of intraperitoneal injection of glucose (2 g/kg of body weight) after 14 h of fasting, and blood was collected from the tail vein periodically over 2 h (fasting, 30 min, 60 min, and 120 min). Plasma insulin concentration was measured by enzyme-linked immunosorbent assay (ELISA) kit specific to insulin (Morinaga Institute of Biological Science). Plasma concentrations of total cholesterol, high density lipoprotein (HDL) cholesterol, and triglyceride were measured by using cholesterol E, HDL cholesterol E, and triglyceride E (Wako Pure Chemical Industries).

Morris Water Maze Test

To assess spatial navigation learning and memory retention, the Morris water maze test was conducted. Initially, animals received a habituation trial during which the animals were allowed to explore the pool of water (diameter 120 cm, height 25 cm, temperature 21 ± 1 °C) without the platform present.

Visual Cue Phase—Following habituation, visible platform training was performed to measure motivation and swimming speed of mice to find a platform. Briefly, distal cues were removed from around the pool, and the platform was labeled with a flag and placed 1 cm above the surface of the water in the center of a quadrant. Mice were placed in the maze and allowed to explore the maze for 60 s, and if they reached the visible platform, they were allowed to remain there for 20 s before being returned to their cages. If they did not find the platform within 60 s, the experimenter led them to the platform and let them remain there for 20 s. Animals were trained in groups of five, and training was completed once each animal received six trials. This training was performed for 1 day.

Acquisition Phase—We measured the ability of mice to understand the spatial relationship between a safe but invisible platform of 10 cm in diameter (submerged 1 cm below the water level) and visual cues surrounding the maze. The platform was located in the center of one of the four quadrants, and several extramaze cues were distributed across the walls surrounding the pool. During the acquisition phase of training, each mouse received four daily hidden platform training trials with 10–12-min intervals for 5 consecutive days. Animals were allowed 60 s to locate the platform and 20 s to rest on it. Mice that failed to find the platform were led there by the experimenter and allowed to rest there for 20 s.

Probe Trial Phase—24 h following the last acquisition trial, a single 60-s probe trial was administered to assess spatial memory retention. For the probe trial, animals were returned to the pool without the platform present, and parameters were recorded to assess the ability of the mouse to remember the previous location of the platform.

Exercise Is More Effective than Diet Control in APP-HFD Mice

Performance was recorded with an automated tracking system (TARGET series/2, Japan) during all phases of training. During the visual cue phase of training, speed and latency to the platform were used to compare the activity of the performance between each group. During the acquisition phase, acquisition time (latency to reach the platform) was used to analyze and compare the performance between different treatment groups. The time to the platform quadrant and the number of entries into the target quadrant were recorded and analyzed during the probe trials.

Immunoblotting and Filter Trap Assay

For immunoblotting analysis, the brain was taken and rapidly frozen using liquid nitrogen. The brain samples from the cerebrum of the male mice were extracted in radioimmunoprecipitation assay buffer (50 mM Tris-HCl, 150 mM NaCl, 1% Triton X-100, 1% Nonidet P-40, 0.5% deoxycholate, 0.1% SDS, pH 8.0) with protease inhibitor mixture (Roche Applied Science) and sufficiently homogenized on ice. Then, the samples were incubated for one night at 4 °C and centrifuged at $14,000 \times g$ for 20 min. The supernatants were directly used for Western blot analysis. The detailed protocol has been described previously (11). 5–20% polyacrylamide gradient gels (Atto) were used to detect full-length APP, β -actin, neprilysin, and insulin-degrading enzyme. Both 5–20% polyacrylamide gradient gels (Atto) and 4–12% NuPAGE Bis-Tris gel (Invitrogen) were used to detect APP CTFs. Mouse monoclonal anti- β -actin and rabbit polyclonal anti-APP C-terminal antibodies were from Sigma. Rabbit polyclonal anti-neprilysin and mouse monoclonal anti-insulin degrading enzyme antibodies were from Abcam.

The filter trap assay was conducted as described previously (7, 12). Briefly, the protein concentration of the cerebrum samples in Tris-buffered saline (TBS)-extracted fraction was measured, and an equal amount of protein was subjected to vacuum filtration through a 96-well dot blot apparatus (Bio-Rad Laboratories) containing 200-nm pore size nitrocellulose membrane. The resultant membrane was then incubated with primary antibody at 4 °C overnight. The membrane was then blocked by TBS containing 4% skim milk and incubated with HRP-linked secondary antibody (GE Healthcare; diluted 1:2,000) for 1 h. The membrane was developed using the ECL Western blotting analysis system (GE Healthcare). Anti-A β oligomer antibody (A11, Invitrogen) was used for the detection of A β oligomer in TBS soluble fraction.

Immunohistochemistry

The paraformaldehyde-fixed and paraffin-embedded tissue sections of male mice were incubated with primary antibodies. The sections were then incubated with biotinylated anti-second IgG antibody (1:2,000; Vector Laboratories) followed by the incubation with avidin peroxidase (ABC Elite kit; 1:4,000; Vector Laboratories). Subsequently, the labeling was visualized by incubation with 50 mM Tris-HCl buffer (pH 7.6) containing 0.02% 3,3-diaminobenzidine and 0.0045% hydrogen peroxide. All images were visually analyzed using an ECLIPSE 80i microscope (Nikon Corp.). For each animal, the sections of the hippocampus were captured then were imported into ImageJ, and an intensity threshold level was set that allowed for discrimina-

tion between the antigen and background labeling. Anti-A β (6E10) antibody (1:1,000; Sigma) was used for the detection of A β plaque.

Neprilysin Activity Assay

The proteolytic activity of neprilysin was measured as described previously with minor modifications (13). Briefly, the brain samples from the cerebrum of the male mice were extracted in radioimmunoprecipitation assay buffer, and protein concentrations were analyzed. 100 μ g of brain lysates were incubated with 50 μ M the substrate 3-dansyl-D-Ala-Gly-p-(nitro)-Phe-Gly (Sigma) and 1 μ M captopril, angiotensin-converting enzyme inhibitor, in 200 μ l of 50 mM Tris-HCl buffer (pH 7.6) for 1 h at 37 °C. Reactions were stopped by heating samples to 100 °C for 5 min followed by $5,000 g \times 5$ min centrifugation. The 180 μ l of supernatant were diluted into 400 μ l of 50 mM Tris-HCl buffer (pH 7.6), and fluorescence was determined using Infinite 200 PRO (Tecan Japan Co., Ltd.) (excitation 342 nm, emission 562 nm).

Statistical Analysis

All values are given in means \pm S.E. Comparisons were performed using an unpaired Student's *t* test. For comparison of multiparametric analysis, one-way factorial analysis of variance followed by the post hoc analysis by Fisher's protected least significant difference was used. Statistical significance of differences between mean scores during acquisition phase of training in the Morris water maze test was assessed with two-way repeated measures analysis of variance (general linear model) and Fisher's post hoc analysis for multiple comparisons. *p* < 0.05 was considered to indicate a significant difference.

RESULTS

Effects of Diet Control on Metabolic Conditions of APP-HFD mice—In our recent study, voluntary exercise is shown to be a useful tool for preventing the progress of cognitive dysfunction and amyloid pathology in APP-HFD mice (7). Notably, voluntary exercise does not ameliorate HFD-induced hyperinsulinemia or hypercholesterolemia but improves glucose intolerance as well as cognitive impairment. Diet therapy is another way to control metabolic dysfunctions. Thus, in the present study, we aimed to elucidate which environmental factor contributes more to metabolic and cognitive functions in APP-HFD mice by controlling the diet (Dc; diet control, APP-HFD+Dc) or combined diet control with exercise (Ex; exercise, APP-HFD+Ex+Dc) after mice were fed HFD for 10 weeks. Then, we compared the effects of these interventions on cognitive function and A β pathology (Fig. 1A).

As reported previously, APP-HFD mice gained significantly more body weight than the control APP mice, and after the introduction of voluntary exercise, APP-HFD+Ex mice gained less body weight than APP-HFD mice (7). On the other hand, the body weight decrease of APP-HFD+Dc and APP-HFD+Ex+Dc mice was much more drastic than that of APP-HFD+Ex mice (Fig. 1B), showing that diet control was more effective in body weight reduction than voluntary exercise. Weekly monitoring of food intake showed that the food intake of the APP-HFD+Dc and APP-HFD+Ex+Dc mice did not

Exercise Is More Effective than Diet Control in APP-HFD Mice

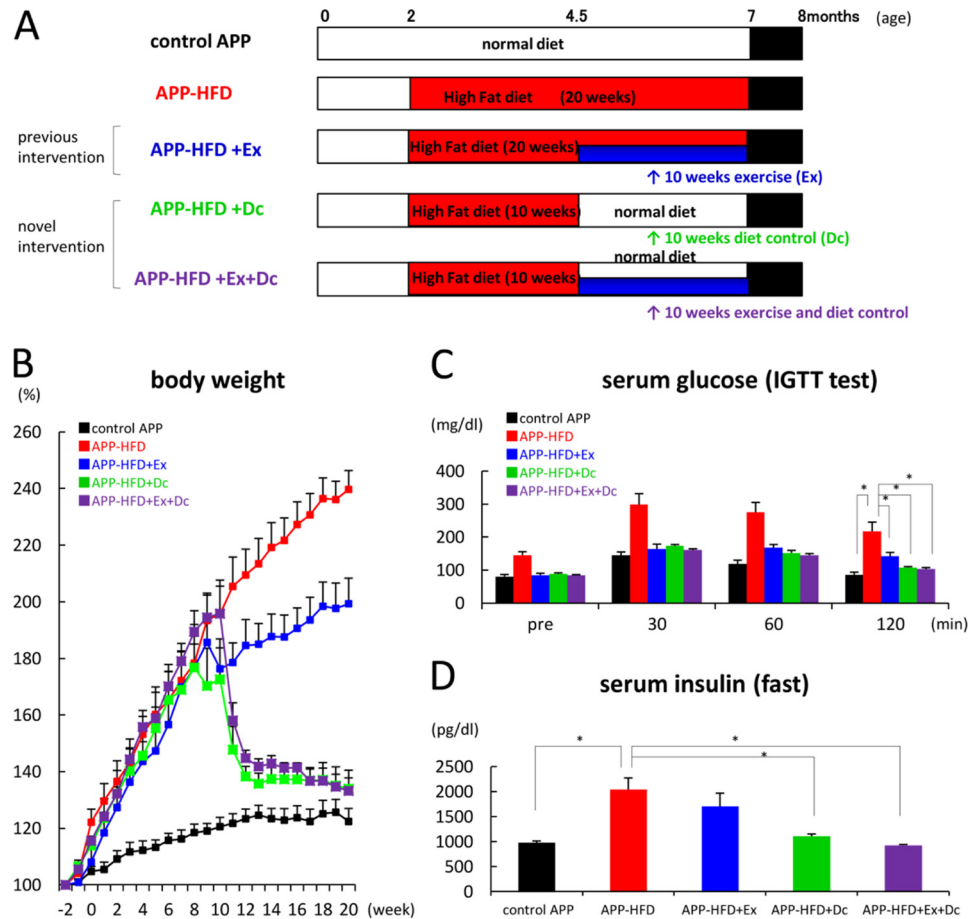

FIGURE 1. Diet control ameliorated HFD-induced obesity and diabetic conditions when compared with exercise. *A*, schematic presentation of the interventions targeting metabolic conditions. As described previously (7), APP^{Swe/Ind} mice were maintained with a standard diet in standard laboratory cages until they were 2–3 months old. Then, age- and sex-matched mice were separated into five groups. In the control group, the mice were fed with a standard diet in standard laboratory cages for 20 weeks (control APP mice) (*top row*, $n = 9$). In the HFD-induced group, mice were fed with a standard diet in standard laboratory cages for 20 weeks (APP-HFD mice) (*second row*, $n = 10$). In the HFD with exercise-induced group, mice spent 10 weeks in standard laboratory cages and then spent 10 weeks in enrichment cages with HFD (APP-HFD + Ex mice) (*third row*, $n = 8$). As a novel intervention, in the diet-control-induced group, after 10 weeks of HFD, we used a standard diet for another 10 weeks (APP-HFD + Dc mice) (*fourth row*, $n = 7$). In the combination group with exercise plus diet control, mice spent 10 weeks in standard laboratory cages with HFD and then spent 10 weeks in enrichment cages with a standard diet (APP-HFD + Ex + Dc mice) (*bottom row*, $n = 7$). After 20 weeks, metabolic conditions of these mice were analyzed followed by ethological, histochemical, and biochemical analyses targeting AD pathophysiology. *B*, relative body weight changes over 20 weeks. The body weight 2 weeks before each diet was regarded as the baseline (100%). Diet control and its combination with exercise significantly inhibited the HFD-induced increase of body weight. *C*, blood glucose levels during glucose tolerance test after an intraperitoneal injection of glucose (2 g/kg of body weight). The fasting glucose level (*pre*) and glucose tolerance in APP-HFD + Dc mice ($F_{(4,159)} = 26.49$, $p < 0.001$) and APP-HFD + Ex + Dc mice ($p < 0.001$) were clearly improved. *D*, serum insulin levels during fasting. The serum insulin levels in APP-HFD + Dc mice ($F_{(4,36)} = 9.3$, $p = 0.003$) and APP-HFD + Ex + Dc mice ($p < 0.001$) were significantly decreased when compared with that in APP-HFD mice.

change or mildly increased (supplemental Fig. 1), indicating that the diet control-mediated attenuation of body weight was not caused by the reduction of food intake. Fasting serum glucose level was not different among APP-HFD + Ex, APP-HFD + Dc, and APP-HFD + Ex + Dc mice, being significantly lower in the three groups than in APP-HFD mice (Fig. 1C, *pre columns*). In addition, the result of the intraperitoneal glucose tolerance test indicated that the impaired glucose tolerance was improved in the APP-HFD + Ex as well as the APP-HFD + Dc and APP-HFD + Ex + Dc mice (Fig. 1C). To examine whether diet control reverses or prevents the development of glucose intolerance, we conducted the intraperitoneal glucose tolerance test 10 weeks after HFD introduction (at the time point when exercise or diet control was started). The fasting glucose level and glucose tolerance of APP-HFD + Dc and APP-HFD + Ex + Dc mice were better than those of APP mice 10 weeks after HFD introduction (supplemental Fig. 2). Therefore,

diet control reversed glucose intolerance as well as exercise did (7). The plasma insulin level of APP-HFD + Dc and APP-HFD + Ex + Dc mice was significantly decreased when compared with that of APP-HFD mice (Fig. 1D). The plasma lipid analyses indicated that both total and HDL-cholesterol were significantly decreased in APP-HFD + Dc and APP-HFD + Ex + Dc mice (Fig. 2, A and B), suggesting that diet control ameliorated HFD-induced hypercholesterolemia. The level of plasma triglycerides was not different among them (Fig. 2C).

Exercise Was More Effective in Ameliorating Memory Deficit of APP-HFD Mice than Diet Control—To compare the effect of diet control on HFD-induced memory deficit with that of exercise, we conducted the Morris water maze test. The locomotor activity of APP mice was not affected by HFD, HFD + Ex, HFD + Dc, or HFD + Ex + Dc, as exemplified by swimming speed (supplemental Fig. 3). During the acquisition phase, APP-HFD + Ex, APP-HFD + Dc, and APP-HFD + Ex + Dc mice

Exercise Is More Effective than Diet Control in APP-HFD Mice

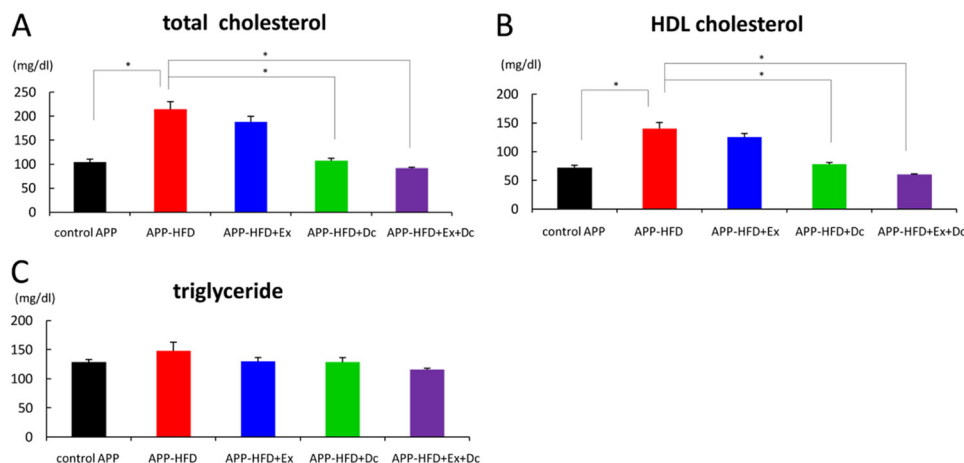

FIGURE 2. Diet control ameliorated HFD-induced lipid dysfunction when compared with exercise. A, plasma total cholesterol levels. The total cholesterol levels in APP-HFD+Dc mice ($F_{(4, 36)} = 30.29$, $^*p < 0.001$) and APP-HFD+Ex+Dc mice ($^*p < 0.001$) were significantly decreased when compared with the level in APP-HFD mice. B, plasma HDL cholesterol levels. The HDL cholesterol levels in APP-HFD+Dc mice ($F_{(4, 36)} = 30.96$, $^*p < 0.001$) and APP-HFD+Ex+Dc mice ($^*p < 0.001$) were significantly decreased when compared with the level in APP-HFD mice. C, plasma triglyceride levels. There was no difference among control, APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice ($F_{(4, 36)} = 1.65$, not significant).

showed a daily improvement in their acquisition time. However, APP-HFD+Dc mice took a longer time to reach the goal than APP-HFD+Ex mice did (Fig. 3A). In the probe trial phase, the time to get to the platform quadrant in APP-HFD+Dc mice was significantly longer than that in APP-HFD+Ex mice (Fig. 3B). Moreover, the number to cross the previous location of the platform in APP-HFD+Dc mice was significantly smaller than that in APP-HFD+Ex mice (Fig. 3C). These results demonstrated that APP-HFD+Dc mice took a longer time to get to the platform quadrant and failed to cross the previous location of the platform when compared with APP-HFD+Ex mice. From these results, we concluded that exercise was the more effective way of ameliorating HFD-induced memory dysfunction than diet control in APP-HFD mice.

A β Pathology of APP-HFD Mice Was Ameliorated Better by Exercise than by Diet Control—Because ample A β deposition is a critical hallmark of AD, we compared the effect of diet control on HFD-induced A β accumulation with that of exercise. For this, we conducted immunohistochemical analysis using anti-A β (6E10) antibody to quantitatively examine A β deposition. As shown in Fig. 4A, A β deposition was aggravated by feeding HFD (7), whereas a marked reduction of HFD-induced A β deposition was observed in APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice. Interestingly, the level of deposited A β in APP-HFD+Ex was significantly lower than that in APP-HFD+Dc mice (Fig. 4B). Therefore, exercise was more effective in reducing A β accumulation than diet control.

An increasing number of studies show that the level of TBS-soluble A β oligomers correlates with memory deficits in AD model mice (2–4). We showed that HFD increases the level of soluble A β oligomers in APP mice, which is reduced by voluntary exercise (7). We further extended this result by comparing the amount of A β oligomers in the above three conditions. The filter trap analysis indicated that the levels of A β oligomers in the APP-HFD+Ex and APP-HFD+Ex+Dc mice were significantly decreased when compared with the level in the APP-HFD mice (Fig. 4, C and D). Remarkably, the level of A β oligomers in the APP-HFD+Ex mice was statis-

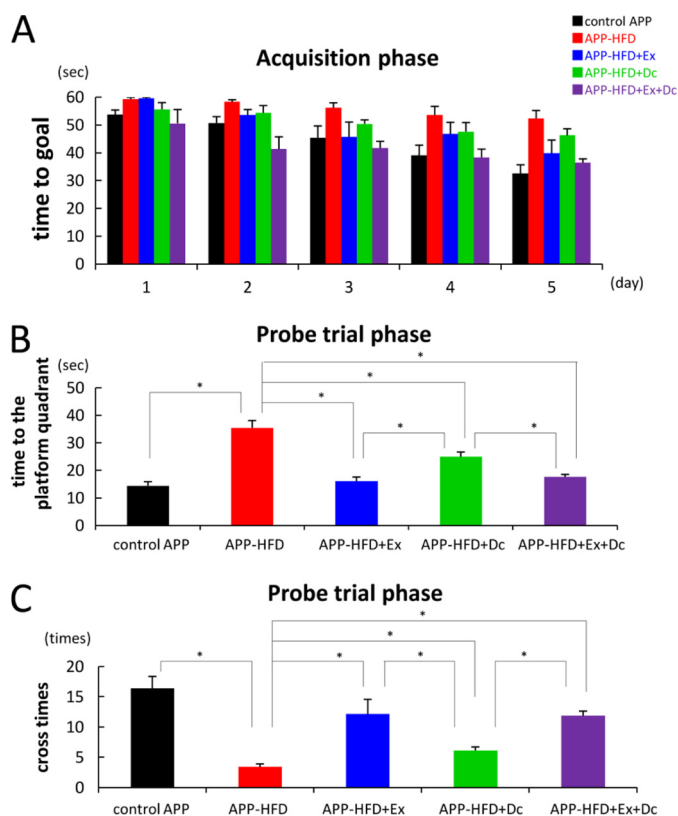

FIGURE 3. Exercise ameliorated HFD-induced memory deficit when compared with diet control. A, escape latency in the acquisition phase. APP-HFD+Ex mice took a shorter time to the platform than APP-HFD+Dc mice. B, the time to the target quadrant in the probe trial phase. APP-HFD+Ex mice took a shorter time to the platform than APP-HFD+Dc mice ($F_{(4, 36)} = 23.03$, $^*p = 0.041$). C, the number of entries into the target quadrant in the probe trial phase. APP-HFD+Dc mice were significantly impaired in the number of times they crossed the platform when compared with APP-HFD+Ex mice ($F_{(4, 36)} = 13.59$, $^*p = 0.013$).

tically lower than that in APP-HFD+Dc mice. Thus, exercise plays a much more significant role than diet control in APP-HFD mice in modulating not only A β deposition but also the level of A β oligomers. This is in line with the result of behavioral experiments.

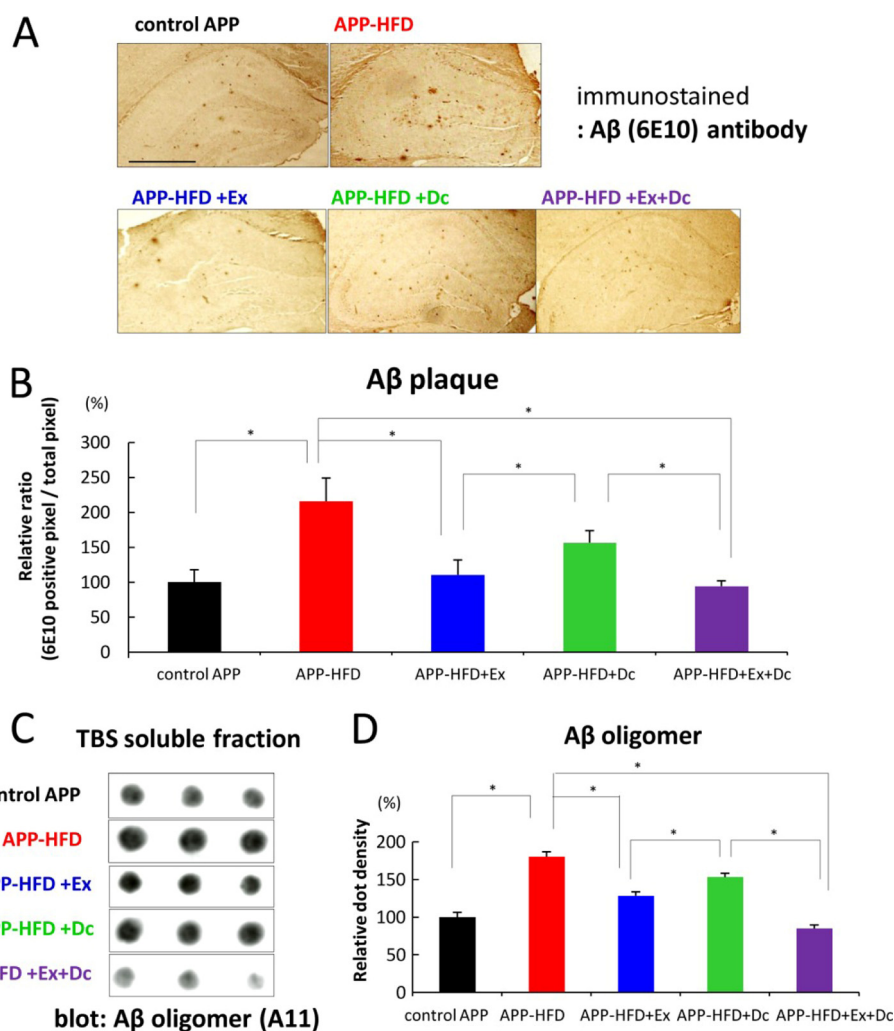

FIGURE 4. Exercise ameliorated HFD-induced Aβ accumulation when compared with diet control. *A*, immunohistochemical analysis using anti-Aβ (6E10) antibody. Representative images of Aβ-immunostained hippocampus sections from control APP, APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc induced mice, respectively, are shown. Scale bar, 2 mm. *B*, cerebral Aβ loads determined by immunohistochemical and morphometric analyses. The cerebral Aβ deposition was significantly decreased in APP-HFD+Ex mice when compared with that in APP-HFD+Dc mice ($F_{(4, 15)} = 18.35$, $p = 0.039$). *C*, the amount of Aβ oligomers in the TBS-soluble fractions of control-APP, APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice analyzed by filter trap assay using anti-Aβ oligomer (A11) antibody. As described in Ref. 12, the Aβ monomer and low weight oligomers passed through the membrane pore (200-nm pore size), and high weight oligomers were detected in this assay. *D*, statistical analysis of dot density. The average band density of the control APP samples was regarded as 100%, and that of other groups was relatively indicated. The relative density of APP-HFD+Ex mice was significantly decreased when compared with that of APP-HFD+Dc mice ($F_{(4, 10)} = 47.42$, $p = 0.011$).

HFD-enhanced APP Processing Was Equally Inhibited by Exercise and by Diet Control—The above results led us to wonder whether the level of Aβ in our mice was regulated by APP processing or by Aβ degradation in exercise/diet control conditions. To examine how these environmental conditions affected the HFD-induced Aβ pathology, we first investigated the effect on APP processing in both conditions and compared the result of exercise with that of diet control. For this, we analyzed the level of APP C terminus fragments through immunoblotting assay using anti-APP C-terminal antibody. APP is cleaved by α- and β-secretases at the extramembrane domain, which produce APP-CTFα and APP-CTFβ, respectively. APP-CTFα and APP-CTFβ were further cleaved by γ-secretase at the intramembrane domain, producing p3 and Aβ, respectively. In the present study, the level of full-length APP was not different among control-APP, APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice (Fig. 5, *A* and *B*).

Moreover, the change of fully glycosylated form was not observed among them. On the other hand, the level of APP-CTFβ in the APP-HFD mice was higher than that in the control APP, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice. Notably, the level of APP-CTFβ in APP-HFD+Ex was the same as that in APP-HFD+Dc mice (Fig. 5, *A* and *C*), indicating that both exercise and diet control inhibited β-secretase-mediated APP cleavage. This tendency was also observed in the level of APP-CTFα (Fig. 5, *A* and *D*).

Neprilysin Activity Was Up-regulated by Exercise—Next, we examined the effect of environmental intervention on Aβ degradation process in APP-HFD mice. Aβ-degrading proteases, including neprilysin, were reported to degrade Aβ both *in vitro* and *in vivo* (14, 15). To compare the effect of exercise on the degradation of Aβ with that of diet control, we analyzed the enzymatic neprilysin activity. As shown in Fig. 6*A*, the activity of neprilysin had a tendency to be suppressed by HFD, although

Exercise Is More Effective than Diet Control in APP-HFD Mice

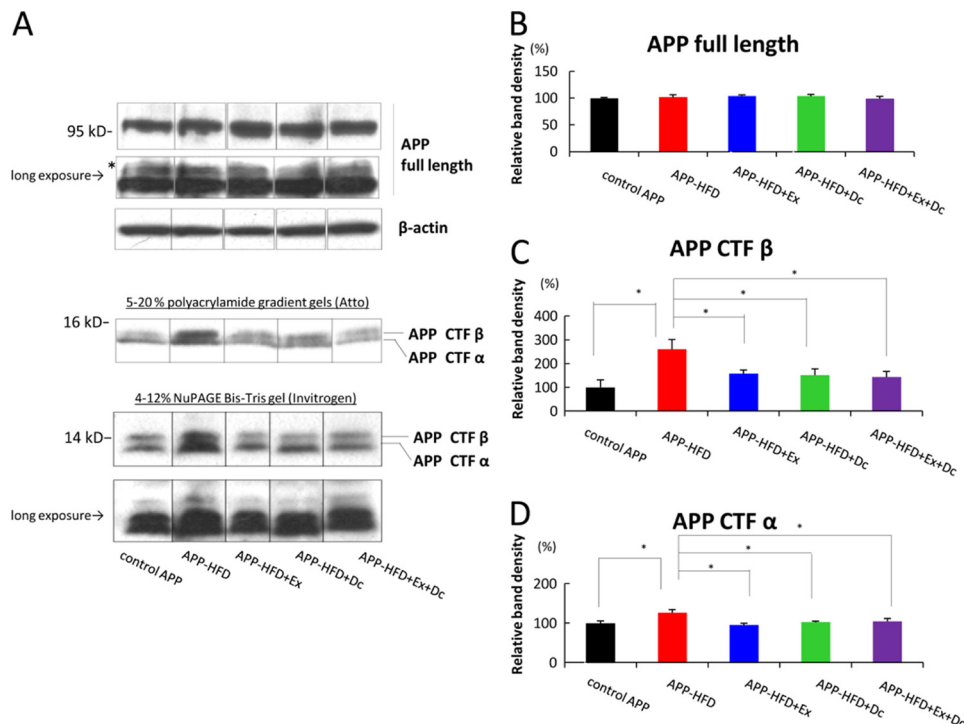

FIGURE 5. Both diet control and exercise reduced APP-CTF β accumulation. *A*, immunoblotting analysis of full-length APP and APP-CTF α and APP-CTF β . Full-length APP and APP CTFs (CTF α and CTF β) were detected by anti-APP C terminus antibody. β -Actin was detected as loading control. *Long exposure* indicated that the same film was exposed for a longer time. The *asterisk* indicates glycosylated full-length APP. To analyze APP CTFs in detail, two kinds of gels (5–20% polyacrylamide gradient gels and 4–12% NuPAGE Bis-Tris gels) were used. Unfortunately, we could not clarify the mobility of CTFs bands caused by phosphorylation presumably because of the gel conditions of our experiment. *B*, statistical analysis of full-length APP. The band of full-length APP was normalized by that of β -actin. The band density of the control was regarded as 100%, and that of other groups was relatively indicated. There was no statistically significant difference among control APP, APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice ($F_{(4,10)} = 0.47$, not significant). *C*, statistical analysis of APP-CTF β . The band of APP-CTF β was normalized by that of full-length APP. The band density of APP-CTF β in APP-HFD mice was increased when compared with that in control APP mice. However, the band densities of APP-CTF β in APP-HFD+Ex ($F_{(4,10)} = 4.27$, $*$, $p = 0.003$), APP-HFD+Dc ($*$, $p = 0.021$), and APP-HFD+Ex+Dc ($*$, $p = 0.023$) mice were significantly decreased when compared with that in APP-HFD mice. There was no difference between APP-CTF β in APP-HFD+Ex mice and that in APP-HFD+Dc mice. *D*, statistical analysis of APP-CTF α . The band of APP-CTF α was normalized by that of full-length APP. The band density of APP-CTF α in APP-HFD mice was increased when compared with that in control APP mice. The band densities of APP-CTF α in APP-HFD+Ex ($F_{(4,10)} = 4.36$, $*$, $p = 0.034$), APP-HFD+Dc ($*$, $p = 0.014$), and APP-HFD+Ex+Dc ($*$, $p = 0.024$) mice were significantly decreased when compared with that in APP-HFD mice. There was no difference between APP-CTF α in APP-HFD+Ex mice and that in APP-HFD+Dc mice.

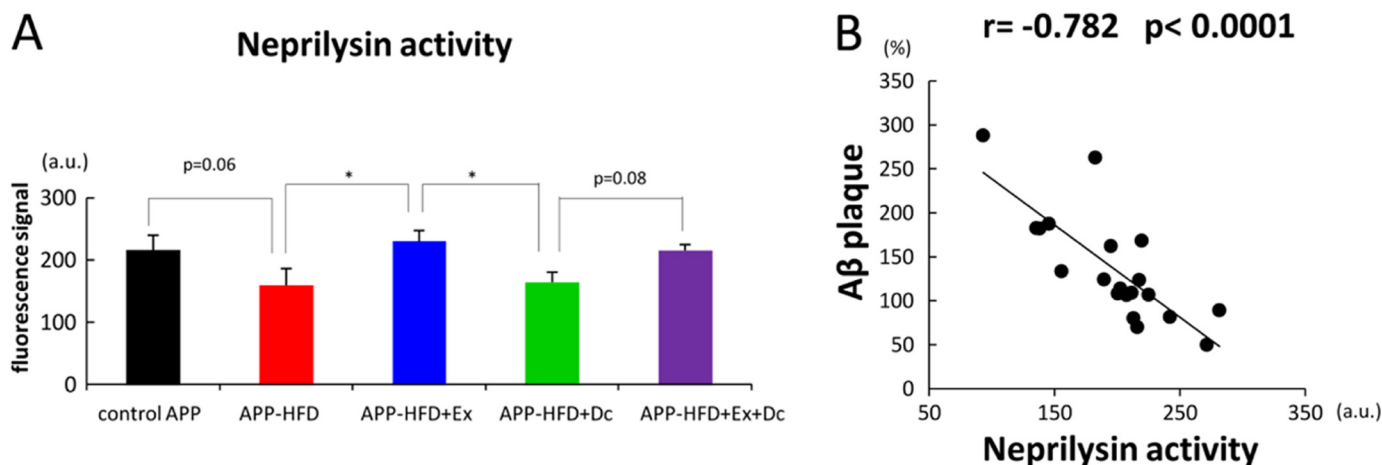

FIGURE 6. Exercise specifically rescued HFD-induced deterioration of neprilysin activity. *A*, *In vitro* enzyme activity assay of neprilysin using the fluorescence substrate. The activity of neprilysin in APP-HFD mice tends to be decreased when compared with that in control APP mice ($F_{(4,15)} = 5.58$, $p = 0.061$). On the other hand, neprilysin activity in APP-HFD+Ex mice was significantly higher than that in APP-HFD mice ($*$, $p = 0.023$) or that in APP-HFD+Dc mice ($*$, $p = 0.032$). *B*, significant correlation was established by comparing the activity of neprilysin and the level of cerebral A β deposition, using Pearson's correlation coefficients. The activity of neprilysin was negatively correlated with the level of accumulated A β ($r = -0.782$, $*$, $p = 0.00003$).

it did not reach statistical significance. More importantly, the enzymatic activity of neprilysin in APP-HFD+Ex mice was significantly higher than that in APP-HFD+Dc mice. On the other hand, the neprilysin activity in APP-HFD+Dc mice was the

same as that in APP-HFD mice. These results indicated that exercise could up-regulate the enzymatic activity of neprilysin. To clarify whether the up-regulation of neprilysin depended on its expression level, we conducted an immunoblotting assay. As

shown in supplemental Fig. 4, the levels of neprilysin were not different among APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice, although those levels were slightly larger than that in control APP mice. In addition, we examined the expression levels of insulin-degrading enzyme, another A β -degrading protease, and determined that its levels were also not different among APP-HFD, APP-HFD+Ex, APP-HFD+Dc, and APP-HFD+Ex+Dc mice. To confirm the effect of neprilysin activity on the A β deposition in our mice, we conducted correlation analysis between neprilysin activity and the level of A β plaque. The activity of neprilysin was significantly correlated with the level of A β deposition (Fig. 6B).

DISCUSSION

HFD is prevalent in modern society, and HFD-induced metabolic conditions are becoming a worldwide issue. Notably, an increasing number of studies have suggested that diet and nutrition are important epigenetic factors for the development of sporadic AD (16–18). Several epidemiological studies have reported that people with a higher body mass index during midlife are at greater risk for developing AD (19–21) and that obesity is associated with lower brain volumes in patients with mild cognitive impairment or AD (22). Obesity promotes a cascade of pathological conditions including type 2 diabetes mellitus and dyslipidemia. Remarkably, several drugs targeting type 2 diabetes mellitus and hypercholesterolemia have been shown to improve cognitive performance in mouse models of AD as well as in patients with early AD (23–26). In our experiment, serum glucose, serum insulin, and serum cholesterol levels were positively correlated with the result of the Morris test in APP-HFD mice, confirming that both type 2 diabetes mellitus and hypercholesterolemia could deteriorate memory deficit in APP mice (supplemental Fig. 5). However, serum glucose level was correlated with memory function in APP-HFD mice better than serum cholesterol and serum insulin levels. In addition, we previously demonstrated that exercise in our experimental condition does not improve HFD-induced hyperinsulinemia and hypercholesterolemia but ameliorates glucose intolerance (7). Therefore, intervention in patients with hyperglycemia and glucose intolerance might be important for the prevention of AD.

Magkos *et al.* (27) reviewed that first-line intervention of metabolic dysfunctions involves lifestyle modifications including diet control and physical activity and that metabolic dysfunctions may be reversible if addressed early on. They proposed that long-term engagement in lifestyle changes may result in the resolution of such dysfunctions (27). However, there has been no solid evidence on whether diet control or exercise is more effective in the prevention of AD. Therefore, in the present study, we aimed to compare the effect of diet control on metabolic dysfunctions as well as AD pathology with that of exercise using APP-HFD mice. Our present study clearly revealed that exercise ameliorated HFD-induced memory impairment better than diet control (Fig. 3). Exercise is reported to enhance neurogenesis and results in increased numbers of synapses per neuron (28). In addition, exercise increases the expression of the brain-derived neurotrophic factor (BDNF), which regulates neuronal development as well as

plasticity (29). In this sense, exercise might specifically induce “cognitive reserve,” which increases cognitive function and enhances complex mental activity as protective factors against dementia (reviewed in Ref. 30). On the other hand, we showed that exercise decreased the level of soluble A β oligomers as well as deposited A β more than diet control (Fig. 4). Thus, the exercise-induced inhibition of A β oligomers might be involved in better cognitive performance in APP-HFD mice because the level of soluble A β oligomers is known to correlate with memory deficits due to their synaptotoxicity (2–4). In line with our present result, Hu *et al.* (28) previously showed that exercise reduces oligomeric A β levels in the cortex and hippocampus of AD model mice. However, there are a couple of differences between our experimental conditions and theirs. Our mice were fed HFD, but their mice were given a standard diet. Moreover, we analyzed oligomeric A β levels after onset of A β deposition, but they examined them before A β accumulation. Therefore, our results clearly supported that exercise reduced oligomeric A β levels after onset of A β deposition even if the mice were fed with HFD.

The level of A β within the brain is determined by the balance between its production and its degradation. Because A β is generated by the proteolytic processing of APP, we first examined whether exercise or diet control was acting directly on A β production. Our detailed immunoblotting analysis showed that the level of APP-CTF β in APP-HFD+Ex mice was almost the same as that in APP-HFD+Dc mice (Fig. 5), indicating that the production of A β might not be different between APP-HFD mice treated with exercise and those treated with diet control. On the contrary, the enzymatic activity of neprilysin, the A β -degrading enzyme, was up-regulated in APP-HFD+Ex mice more than in APP-HFD+Dc mice (Fig. 6). Lazarov *et al.* (31) have reported that voluntary exercise elevates neprilysin activity in the brain of APP transgenic mice, contributing to the lowering of A β levels, which is in line with our findings. However, their result is different from ours in that their APP mice, which were allowed voluntary exercise, were fed a standard diet. Intriguingly, we found that feeding HFD itself reduced the activity of neprilysin. We further observed that exercise strengthened neprilysin activity even if the mice were fed with HFD. In the present study, the activity of neprilysin was negatively correlated with the level of deposited A β (Fig. 6). Therefore, we assumed that exercise-mediated up-regulation of neprilysin may critically reduce HFD-induced A β deposition. Importantly, the expression level of neprilysin did not change between the exercise- and the diet control-treated APP-HFD mice (supplemental Fig. 4). Because the activity of neprilysin was clearly up-regulated by exercise only, we concluded that exercise could modulate its activity in an expression level-independent manner. We speculate that exercise may specifically modulate the upstream molecules of neprilysin or may regulate posttranslational modification of neprilysin. The mechanism of neprilysin up-regulation by exercise should be clarified in future studies.

As classified in Fig. 7A, our result, for the first time, clarified the differential effects of diet control and exercise on metabolic and cognitive dysfunctions. According to our data, diet control significantly improved HFD-induced metabolic conditions, including obesity, hyperinsulinemia, and hypercholesterolemia

Exercise Is More Effective than Diet Control in APP-HFD Mice

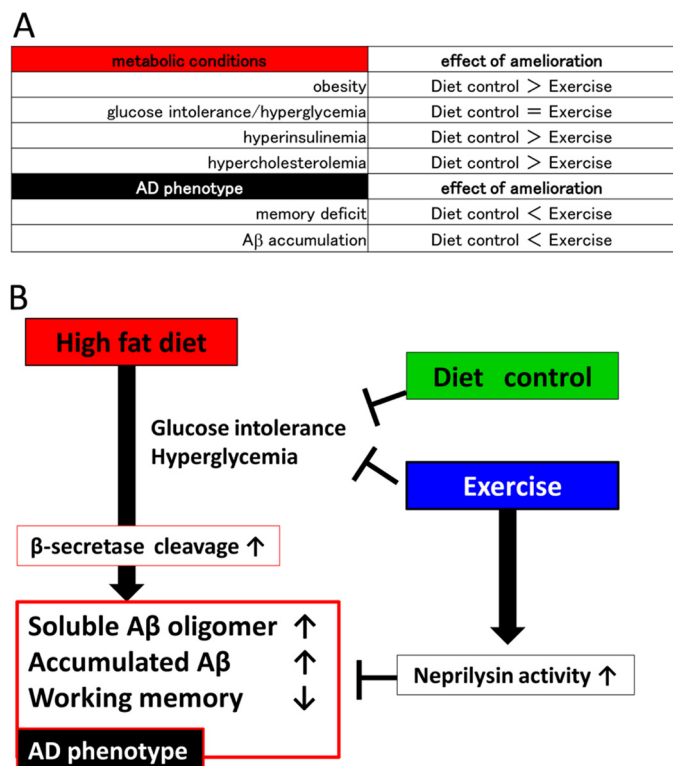

FIGURE 7. Schematic presentation of our study. *A*, the classification of the results in the present study. The items we analyzed in this study are included in the *left column*, whereas the effect of amelioration is shown in the *right column*. As shown in this table, *Diet control > Exercise* indicated that diet control ameliorated better than exercise. Diet control significantly improved HFD-induced metabolic conditions, including obesity, hyperinsulinemia, and hypercholesterolemia, better than exercise. However, exercise decreased soluble A β oligomers as well as deposited A β and ameliorated memory impairment better than diet control. *B*, schematic presentation of our hypothesis: how diet control or exercise ameliorated HFD-induced memory deficits and A β accumulation. HFD leads to glucose intolerance and hyperglycemia, which may lead to the up-regulation of β -secretase activity. This up-regulation increases soluble A β oligomers as well as deposited A β levels followed by memory deficit (7). On the other hand, both diet control and exercise ameliorate HFD-induced glucose intolerance and hyperglycemia, thereby decreasing soluble A β oligomer and fibrillar A β levels by inhibiting A β production. However, exercise specifically strengthens the enzymatic activity of neprilysin, which degrades A β in the brain.

(Figs. 1 and 2), when compared with exercise. However, exercise decreased A β oligomers as well as deposited A β (Fig. 4) and ameliorated memory impairment (Fig. 3) when compared with diet control. From these results, we conclude that exercise was more effective than diet control in the prevention of HFD-induced amyloid pathology. In Fig. 7*B*, we present our hypothesis on how diet control and exercise differently ameliorate HFD-induced A β deposition and memory deficit in APP transgenic mice. As described in our previous study, HFD leads to glucose intolerance and hyperglycemia, which may lead to the up-regulation of β -secretase activity. This up-regulation increases soluble A β oligomers as well as deposited A β levels followed by memory deficit (7). The up-regulation of β -secretase was also reported in HFD-feeding mice from another laboratory (32) and consistently reported in AD cases by several previous studies (33–35). Thus, this phenomenon might represent the actual pathology of sporadic AD. On the other hand, both diet control and exercise ameliorate HFD-induced glucose intolerance and hyperglycemia, thereby decreasing A β load by inhibiting A β

production. However, exercise specifically strengthens the enzymatic activity of neprilysin, which decreases the level of A β in the brain. Surprisingly, the effect of the combination treatment (exercise and diet control) on cognitive function and amyloid pathology was not significantly different from that of exercise only, indicating that exercise is an effective behavioral intervention sufficient to inhibit A β pathology. We suppose that this is because exercise affects both the production and the degradation of A β , but diet control modifies only the production of A β . Therefore, for the introduction of intervening metabolic functions targeting the prevention of AD, we provide the first evidence-based comparison of effective interventions, concluding that exercise has the highest priority. Although the beneficial effect of exercise was obtained even under HFD, the magnitude and the nature (*i.e.* voluntary *versus* forced, aerobic *versus* anaerobic) of the exercise required to prevent HFD-induced AD progression should be elucidated in future studies. Because metabolic dysfunctions are epidemiologically considered to be risk factors of sporadic AD, evidence-based interventions for metabolic dysfunctions should be carried out to prevent AD.

Acknowledgments—We appreciate Dr. S. Oka (Kyoto University, Kyoto, Japan), Mr. J. Morise (Kyoto University), Dr. Y. Kitamura (Kyoto Pharmaceutical University, Kyoto, Japan), and Dr. K. Takata (Kyoto Pharmaceutical University) for technical assistance in the brain sample preparation. We thank Dr. K. Saito (Kyoto University) for kind support of the Morris water maze test. We greatly appreciate the advice for metabolic analysis from Dr. M. Okuda (PHARMAEIGHT, Kyoto, Japan). We thank Dr. Y. Tashiro (Kyoto University) for kind discussion.
