Abstract

The genus *Empodisma* comprises two species that are ecologically important in wetland habitats. *Empodisma gracillimum* is restricted to south-western Australia, whereas *E. minus* is found in Tasmania, eastern Australia and New Zealand. We sequenced three cpDNA genes for 15 individuals of *Empodisma* sampled from throughout the range of the species. The results support an Australian origin for *Empodisma* sometime during the late Oligocene to early Miocene with more recent dispersal, colonization and diversification in New Zealand. We recovered six genetically distinct maternal lineages: three *E. gracillimum* haplotypes corresponding to the three accessions in our analysis, a wide-ranging *E. minus* haplotype found in eastern Australia and Tasmania, an *E. minus* haplotype found in New Zealand from Stewart Island to approximately 38° S latitude on the North Island, and a distinct haplotype restricted to the North Island of New Zealand north of 38° S latitude. The Eastern Australian and New Zealand haplotypes of *E. minus* were supported by only one cpDNA gene, and we felt the relatively minor morphological differences and the small amount of genetic divergence did not warrant taxonomic recognition. However, we recommend that the northern New Zealand haplotype should be recognized as the new species *Empodisma robustum* and provide descriptions and a key to the species of *Empodisma*. Monophyly of *E. robustum* is supported by all three cpDNA genes. *Empodisma robustum* can be distinguished from *E. gracillimum* and *E. minus* by its robust growth stature and distinct ecology. It is typically eliminated by fire and re-establishes by seed (seeder strategy), whereas *E. minus* and *E. gracillimum* regrow after fire (sprouter strategy).

Restionaceae, *Empodisma*, taxonomy, new species, New Zealand

Introduction

As presently circumscribed, the genus *Empodisma* L.A.S.Johnson & D.F.Cutler (Restionaceae) comprises two species with a widely disjunct distribution in western Australia and south eastern Australia, Tasmania, and New Zealand. *Empodisma gracillimum* (F.Muell.) L.A.S.Johnson & D.F.Cutler is found on the coastal plain from Perth southwards, and along the south coast from Augusta to Albany (Fig. 1), while *E. minus* (Hook.f.) L.A.S.Johnson & D.F.Cutler is found in lowland to alpine zones from Queensland to South Australia, Tasmania and throughout most of New Zealand in New Zealand. They probably diversified in seasonally wet habitats, but exhibit adaptations to seasonal drought, fire and nutrient poor soils (Linder and Rudall 2005).

The species of *Empodisma* are plants of peatlands, particularly raised bogs, blanket bogs, fens, and wet heathlands (Meney and Pate 1999, Johnson and Brooke 1989, Johnson and Gerbeaux 2004). The scientific name is derived from the Greek word for obstacle or hindrance (Johnson and Cutler 1973), and because of their tendency to form dense masses of tangled culms they are also given the common name wire rush. They are rhizomatous perennials with evergreen culms. The horizontal roots branch profusely to form cluster roots (Lamont 1982), i.e. finely divided rootlets with persistent root hairs. The underlying peat is formed mainly from the remains of this densely branched root matrix, which binds litter and bryophytes into the peat (Campbell 1964). The cluster roots retain water like a sponge, up to 15 times their dry weight, and like *Sphagnum* they create acidic conditions (Campbell 1964, 1975, Agnew et al. 1993). In this type of environment incoming rainfall and atmospheric particulates are the major sources of nutrients, which are efficiently removed by the cluster roots of *Empodisma* at the bog surface (Clarkson et al. 2009).

Fire plays an important role in the development of restiad peat bogs in both Australia and New Zealand. For the most part, the species of *Empodisma* are “sprouters” (Pate et al. 1991, Meney et al. 1997, Meney and Pate 1999). In sprouters most of the carbon resources and nutrient elements are allocated towards maintenance and vegetative growth. The underground portions of individual plants are protected and survive fire, and regeneration occurs by the sprouting of new leafy shoots produced from the rhizome system. This contrasts with an obligate “seeder” strategy whereby the plants are killed by fire and re-establish from seed. Seeders generally produce more delicate, less extensive underground rhizome systems and have perennating buds higher in the soil, and without a requirement for nourishing the developing rhizomes, more resources can be allocated to seeds. However, this distinction is not as clear in habitats that experience waterlogged soils during the wet season but have a long intervening dry season, as occurs in much of Australia (Pate et al. 1999).

The taxonomic history of *Empodisma* is complex. The species of *Empodisma* were originally placed in *Calorophus* Labill or *Hypolaena* R.Br. by early taxonomists classifying Restionaceae (Labillardière 1806, Brown 1810, Hooker 1852–1853, Hooker 1857–58, Mueller 1872–1874, Bentham 1878, Cheeseman 1906, Cockayne 1958, Moore and Edgar 1970). The genus *Calorophus* Labill. was originally described by Labillardière (1806). When first de-

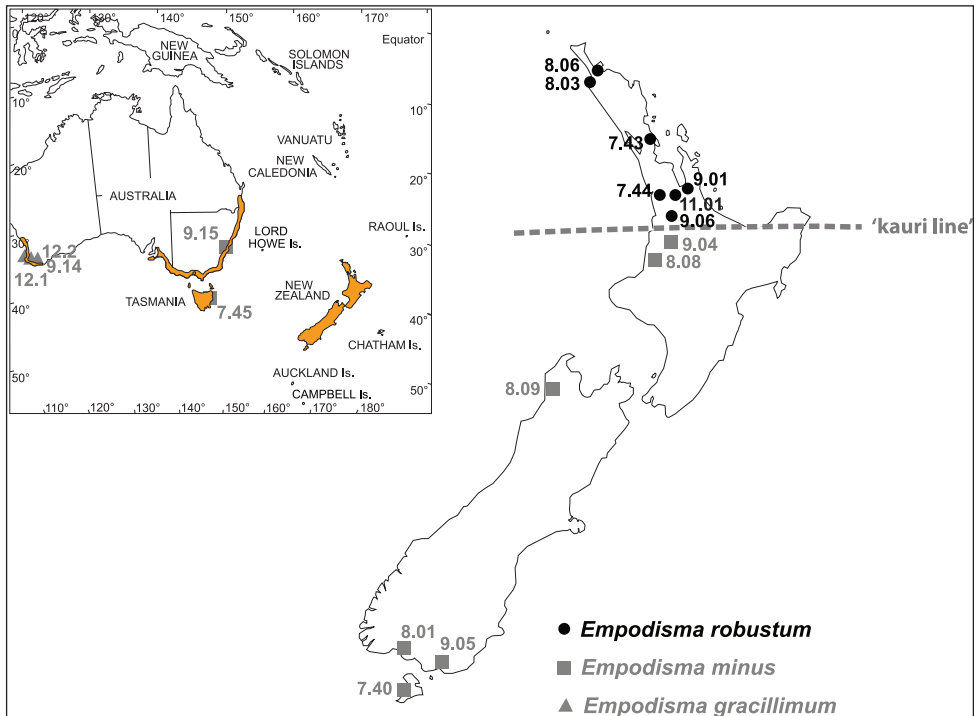

Figure 1. Map showing the generalized distribution of *Empodisma* in Australia and New Zealand and the collection localities of the DNA samples included in our study. The approximate position of the kauri line in New Zealand is shown with a dashed line.

scribed the Tasmanian species *C. elongatus* was the sole member of the genus and is the type. In his first treatment of the flora of New Zealand, Hooker (1853) described a new species of *Calorophus*, *C. minor* Hook.f., based upon Bidwell, Colenso and Lyall specimens. A specimen of *C. minor* collected on the South Island of New Zealand near Nelson by Bidwell was designated as the lectotype by Moore and Edgar (1970). However, in his treatment of the Flora of Tasmania, Hooker (1859) relegated *C. minor* Hook.f. as the variety *C. elongatus* var. *minor* (Hook.f.) Hook.f. Mueller (1872–74) distinguished the plants from western Australia as the distinct species *C. gracillimus* F. Muell., but in *Flora Australiensis* Bentham (1878) followed Brown's (1810) earlier treatment, which reduced *Calorophus* to sectional rank within the genus *Hypolaena*. Bentham's treatment was subsequently followed by Cheeseman (1906) and Cockayne (1958) who recognized the New Zealand plants as *Hypolaena lateriflora* var. *minor* (Hook.f.) Cheesem. However, Moore and Edgar (1970) followed Hooker's (1859) treatment, adopting the name *Calorophus minor* Hook.f. in their treatment of the Flora of New Zealand, Vol. II. Based on anatomical, morphological and cytological differences among the species of *Calorophus*, Johnson and Cutler (1973) subsequently erected the genus *Empodisma* L.A.S.Johnson & D.F.Cutler to accommodate *E. gracillimum* and *E. minus*.

The specimen upon which Hooker based the name *Calorophus minor* is a small slender plant characteristic of alpine regions found in South Island and Stewart Island

of New Zealand. Moore and Edgar (1970) noted that plants at lower elevation in the lowland bogs near Cambridge in the Waikato, northern North Island, were larger and more robust, but based upon study of herbarium specimens they felt the variation was continuous from low to high elevation. We provide evidence for an alternative taxonomic interpretation. The lowland populations of *Empodisma* north of the “kauri line” (the southern limit of *Agathis australis* (D. Don) Lindl. ex Loudon is approximately 38° S latitude in New Zealand) comprise a distinct evolutionary lineage that we here recognize as *Empodisma robustum* S.J. Wagstaff & B.R. Clarkson, sp. nov.

Methods

Study group

We conducted a global analysis of 48 members of the Restionaceae to test monophyly of *Empodisma* and its relationships to *Calorophus* and *Hypoleana*. Three genera of Anarthriaceae (*Anarthria* R. Br., *Hopkinsia* W. Fitzg. and *Lyginia* R. Br.) were selected as outgroups. Intraspecific variation within *Empodisma* was assessed by comparing DNA sequences from 18 accessions collected from throughout the range of these species (Fig. 1).

Data resources

Voucher specimens with their collection locality and GenBank accession numbers are listed in Appendix 1. The aligned data matrices have been submitted in Nexus format to TreeBase matrix accession number <http://purl.org/phylo/treebase/phylovs/study/TB2:S12748> and the Dryad repository: doi: 10.5061/dryad.94710.

Morphological analyses

A single set of morphological measurements were taken from each of 76 dried herbarium specimens on loan from AK, CHR, WAIK, WELT and PERTH (abbreviations follow Index Herbariorum). The morphological measurements describe the growth habit and floral structures of *Empodisma* and were confirmed with additional observations from field collections. Because *Empodisma* is dioecious, floral attributes of female flowers were coded as missing on male plants. Also very few specimens had mature fruits, and this attribute was also coded as missing from many specimens. We used GenStat version 8.1.0.152 (supplied by VSN International Ltd., www.vsn-int.com) to illustrate patterns of variation among the characters (listed in Fig. 6) using BOXPLOTS and PRINCIPAL COORDINATES ANALYSIS (PCoA). Principal coordinates analysis depicts relationships among the 91 Operational Taxonomic Units (OTU's) that comprised our sample. We initially generated

a similarity matrix of Euclidean distances then created a two-dimensional ordination. The first axis accounted most of the variation with less variation described by the second axis.

To test the influence of environmental conditions on growth form, we set up a common garden experiment by transplanting individuals ($n=3$) from New Zealand sites representing populations of both large (*E. robustum*) and small (*E. minus*) growth forms to Hamilton, North Island (37°47'S latitude). The sites selected were Torehape (37°18'S), Kopuatai (37°24'S), and Moanatuatua (37°55'S) for the large growth form, and Tongariro (39°16'S), Rangipo (39°22'S), and Awarua (46°33'S) for the small form. Ecological information was summarized from the published literature and unpublished data of BRC.

DNA extraction, amplification and sequencing

We extracted total DNA from either freshly collected plants or plants dried using silica gel, using a Qiagen DNeasy extraction kit (QIAGEN Pty Inc., Clifton Hill, Victoria, Australia) following the manufacturer's directions. Three chloroplast-encoded DNA regions were sequenced: *rbcl*, *matK* and *trnL*. These regions were selected as they have been used previously to resolve relationships within the Restionaceae (Briggs et al. 2000, 2010, Linder et al. 2003, Hardy and Linder 2005, Moline and Linder 2005, Givnish et al. 2010). The genes *rbcl* and *matK* encode functional proteins, whereas *trnL* encodes part of the gene for Phe-tRNA along with the intervening intron. With very few exceptions chloroplast genes are maternally inherited in flowering plants, so sequence differences correspond to unique haplotypes.

Our PCR amplification and sequencing procedures generally followed those described by Linder et al. (2003) and Hardy and Linder (2005). Excess primers and unincorporated nucleotides were removed from PCR products by a Shrimp Alkaline Phosphatase (GE Healthcare, Global Headquarters, Calfont St Giles, UK)/Exonuclease I (Fermentase International Inc, Burlington, ON, Canada) treatment. Sequencing reactions were run on an ABI3730 sequencer (Applied Biosystems, Foster City, CA, USA) by the Allan Wilson Centre Genome Service at Massey University, Palmerston North, New Zealand. In all instances we sequenced both the forward and reverse DNA strands. The sequence contigs were edited using Sequencher 4.8 (Gene Codes Corporation, Ann Arbor, MI, USA).

Sequence alignment

We used ClustalX (Thompson et al. 1997) to facilitate alignment of the sequences. The sequence alignments for *matK* and *rbcl* were easily achieved as there no gaps in the *rbcl* and only two gaps in the *matK* matrix. The gaps in *matK* occurred in multiples of three and were positioned so as not to disrupt the codon reading frame. The *trnL* sequence alignment across the Restionaceae was more complex, so we used a modification of the sequence profile alignment procedure described by Morrison (2006).

Closely related sequences were initially aligned using the multiple alignment settings, a gap opening penalty of 5, a gap extension penalty of 5, and a delay-divergent-sequences setting of 97%. These ClustalX penalties favour opening gaps rather than substitutions, and they delayed adding the most distantly related taxa in our study. We identified low-scoring segments and exceptional residues, using the quality settings in ClustalX, and reconciled alternative alignments of these short DNA stretches. The final alignments were then visually inspected, and minor adjustments were made manually before conducting the phylogenetic analyses.

Some of the outgroup sequences were not available from GenBank (e.g. a *matK* sequence was missing for *Chordifex hookeri* (D.I.Morris) B.G.Briggs, but both an *rbcL* and *trnL* sequence were available from GenBank for this taxon). Rather than excluding these taxa, the incomplete data partitions were coded as missing. Many recent empirical and simulated studies suggest that it is possible to include taxa with large amounts of missing data without compromising phylogenetic accuracy. Indeed, increasing both the number of taxa and characters can improve the accuracy of phylogenetic inferences (Weins and Morrill 2011).

Parsimony and median network analyses

We conducted both parsimony and network analyses of the sequence data sets, using PAUP* 4.0b10 (Swofford 2002) and SplitsTree version 4.8 (Huson 1998, Huson and Bryant 2006). For the parsimony searches we used the settings TBR branch swapping, MULPARS in effect, and RANDOM ADDITION with 1000 replicates. The parsimony characters were unordered and equally weighted. Duplicate trees were eliminated using the “condense trees” option collapsing branches with a maximum length of zero. Congruence of the data partitions was assessed using the Incongruence Length Difference (ILD) test (Farris et al. 1994, 1995) with 100 data partition replicates excluding uninformative sites as suggested by Hipp et al. (2004) and Ramirez (2006). Taxa that were missing one or more of the data partitions were excluded from the ILD test. In the absence of significant conflict, we combined the sequence data sets. Support for clades was estimated by bootstrap (Felsenstein 1985, 1988) with 1000 replications excluding uninformative sites; starting trees were obtained by RANDOM ADDITION with one replication for each bootstrap replicate, TBR branch swapping, and MULPARS in effect. Median networks were constructed using the options add all trivial characters and a minimum support value of 1.

Bayesian analysis and divergence estimates

Each gene partition was tested for the best substitution model using jModelTest (Posada 2008) with default settings based on the Bayesian Information Criterion (BIC) (Posada

and Buckley 2004), averaging over all included parameters in order avoid a bias towards parameter-rich models. The jModelTest comparisons selected TrN + I + G as the best fit model for *rbcL*, TPM1 for *matK* and TIM1ef for *trnL*. Because the genes *rbcL* and *matK* encode functional enzymes, we unlinked the substitution rate parameters and the base frequencies across codon positions (1+2), 3. Most of the synonymous mutations occur in the third codon position. The aligned matrices were then prepared as output files for analysis in BEAUti 1.6.1 (part of the BEAST package) and analyzed in BEAST 1.6.1 (Drummond and Rambaut 2007). A Yule prior (Yule 1924) was set for the tree model, together with unlinked relaxed lognormal clock models on the substitution rates for each locus. The MCMC chains were set to run for 90 million generations, logging parameters every 1000 generations. Chain mixing and convergences were checked in Tracer v1.5 (Rambaut and Drummond 2007) with all parameters showing ESS values of > 200. A maximum clade credibility trees was calculated using TreeAnnotator 1.6.1 (Drummond and Rambaut 2007) and a summary with 95% highest posterior density intervals of divergence time estimates was prepared using FigTree v1.3.1 (Rambaut 2009).

Incorporating uncertainty associated with the fossil record

The earliest verifiable fossils of Poales are from the early Cretaceous (Maastrichtian) deposits dated approximately 115 million years ago (Herendeen and Crane 1995). The Restionaceae are nested within the Poales, so it is unlikely that the age of the restiad lineage is older than 115 million years. The earliest restiad microfossils appear in late Cretaceous deposits in South Africa dated between 64 and 71 million years ago (Scholz 1985) with fossils appearing in progressively younger deposits in Antarctica, Australia, New Zealand and South America (Truswell and MacPhail 2009, Barreda and Palazzesi 2007, MacPhail 1997, Scholz 1985, Mildenhall 1980). We attempted to incorporate uncertainty associated with these fossil calibrations by applying a lognormal prior with an offset of 115, a log mean = 2 and a log (Sdev) = 0.5 applied to the root and an offset of 64, a log (mean) = 2 and a log (Sdev) = 0.5 to the node separating the Anarthriaceae from the Restionaceae. These settings provide broad probability distributions between 117.8–134.7 and 66.8–83.7.5, with median values of 118.2 and 71.4 respectively for these calibration points.

Results

The combined sequence data set comprised three data partitions with a total of 4267 characters; approximately 23% of the total data matrix was comprised of gap or missing data. An ILD test of the three data partitions failed to find significant conflict ($p = 1-82/100 = 0.18$). A heuristic search with parsimony as the optimality criterion recovered a single island of 180 trees of 2226 steps (Consistency Index (CI) = 0.607 (excluding uninformative characters); Retention Index = 0.788); a strict consensus is shown in Fig. 2. The three

Figure 2. Strict consensus tree. The three species of *Empodisma* (highlighted in bold) emerge as a well-supported clade distinct from *Calorophus* and *Hypolaena*. They were placed in these latter two genera by Moore and Edgar (1970) and Cheeseman (1906). Bootstrap values are provided above the branches

gene regions differed in length, the number of variable characters, and the degree to which they resolved and supported phylogenetic relationships.

The strict consensus tree (Fig. 2) agrees with the subfamilial classification of Briggs and Linder (2009). *Restio distichus* is the only representative of Restionioideae (Afri-

can); *Calorophus*, *Sporadanthus* and *Lepyrodia* (Australian) make up Sporadanthoideae, while the remainder are representative of Leptocarpoideae. In our analysis the three species of *Empodisma* form a well-supported clade (100% bootstrap) with *E. gracillimum* emerging as sister to *E. minus* and *E. robustum*. *Winifredia sola* is weakly supported as sister to *Empodisma*, and *Taraxis grossa* emerges as sister to the *Empodisma* *Winifredia* clade (99% bootstrap). The two species of *Calorophus* also form a well-supported clade (100% bootstrap), but are distantly related to *Empodisma*, instead emerging as sister (100% bootstrap) to *Sporadanthus*. Likewise *Hypolaena* is also distinct from *Empodisma*. The species of *Hypolaena* are nested within a large clade (92% bootstrap) that includes *Apodasmia* and *Alexgeorgea subterranean* Carlquist.

The maximum parsimony and Bayesian analyses converged on trees with essentially the same topology, which suggested that the sequence data are robust to the different assumptions associated with these two approaches. Notably, the Bayesian posterior probability values were generally higher than the bootstrap support values, and the chronogram was better resolved (Fig. 3). The 95% highest posterior density estimates revealed substantial uncertainty associated with the divergence estimates, so our results should be viewed as preliminary. The results suggest *Empodisma* diverged from its most closely related ancestor (MCRA), *Winifredia sola* L.A.S. Johnson & B.G. Briggs approximately 21.8 (15.9–28.2) million years ago (mya). *Empodisma gracillimum* diverged at about 8.8 (5.4–12.9) mya and *E. robustum* split from *E. minus* approximately 2.0 (0.8–3.8) mya. Even though the algorithm for dating divergence times was different, the estimates presented here are similar to those obtained by Linder et al. (2003).

A comparison of median networks assessing levels of intraspecific variation in the three species of *Empodisma* is shown in Fig. 4. In each instance only a single parsimony tree was recovered. The *trnL* sequences were the shortest but the most variable. They were 953 nucleotides in length, and of these, 18 substitutions were parsimony informative. Fourteen substitutions supported the *Empodisma gracillimum* lineage with two unique parsimony uninformative substitutions distinguishing *E. gracillimum* 9.14 from the other species. One *trnL* character supported the eight accessions of *E. minus* (bootstrap 63%). The split between the Australian (*E. minus* 7.45 and *E. minus* 9.15) and the New Zealand specimens (*E. minus* 8.09, *E. minus* 9.05), was supported by one *trnL* character but again with low support (65% bootstrap). Two informative substitutions supported the split between the robust northern New Zealand specimens of *Empodisma* (e.g. *E. robustum* 9.06 and *E. robustum* 7.44) highlighted in bold and the other specimens of *Empodisma* in our data set (Fig. 4). Further support for this split comes from a 23-base duplication that is absent from *E. robustum* but present in *E. minus* and *E. gracillimum*. This split received 86% bootstrap support in our analysis. The sequences were identical within the seven accessions of *E. robustum*.

The *rbcL* sequences were 1401 nucleotides long; of these, eight characters were parsimony informative and 1393 were constant. The informative characters support four splits in the data (Fig. 4). Five substitutions support *E. gracillimum* with one substitution supporting *E. gracillimum* 12.1 and *E. gracillimum* 12.2. The third split sup-

Figure 3. Bayesian chronogram with estimated divergence times. Node error bars are provided in blue showing the 95% highest probability density for the divergence estimates. Posterior probability support values > 97% are given above the branches. A geological time scale is shown at the base of the tree.

ports only the diminutive accessions of *E. minus* from New Zealand (65% bootstrap), and one substitution supports the fourth split separating the large lowland form of *Empodisma* (e.g. *E. robustum*7.43 highlighted in bold (68% bootstrap).

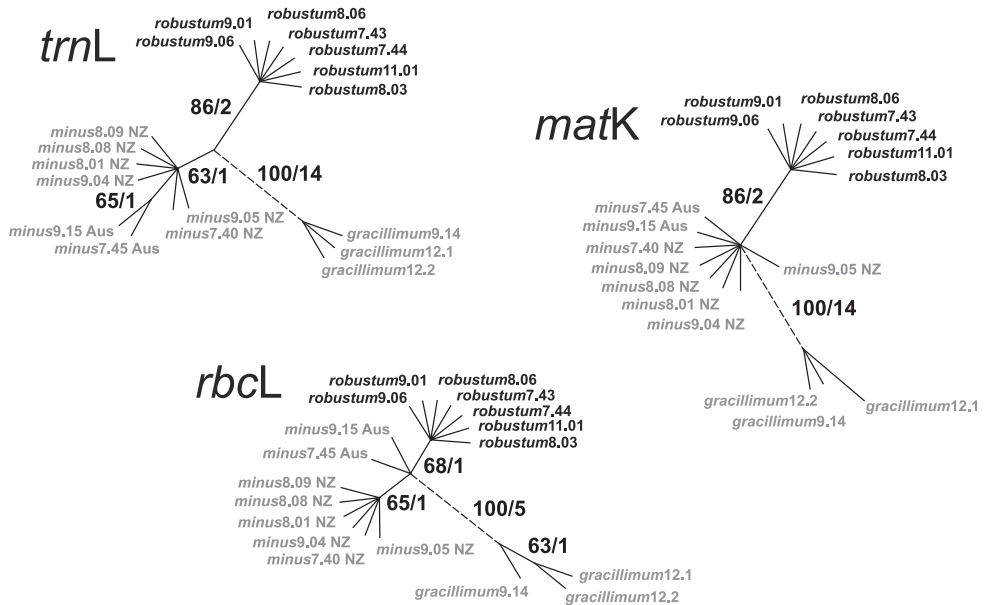

Figure 4. Comparison of median networks from independent analyses of *trnL*, *rbcL* and *matK* sequences. Bootstrap values / the number of mutations distinguishing each haplotype, are shown beside the branches. The accessions of *Empodisma minus* from New Zealand and Australia Aus.

By comparison, the *matK* sequences were 1469 nucleotides long, and of these 16 characters were parsimony informative, 3 variable characters were parsimony uninformative, and 1450 were constant. The informative characters again provided strong support for the split between *E. gracillimum* and the remaining samples in our data (14 substitutions/100% bootstrap) (Fig. 4). *E. gracillimum*12.1 was supported by two unique substitutions and *E. gracillimum*9.14 by one. The split between specimens of *E. robustum* from northern New Zealand and *E. minus* was supported by 2 substitutions / 86% bootstrap. The sequences within these latter two groups were identical.

The Incongruence Length Difference test failed to reveal significant incongruence ($p = 1 - 1/100 = 1.00$) among the three independent data sets, so we pooled them. An analysis of the combined data recovered a single maximum parsimony tree; an unrooted phylogram is shown in Fig. 5 (Consistency Index, excluding uninformative characters = 1.00, Retention Index = 1.00). The combined analysis provided strong support for clades corresponding to the western Australian endemic, *Empodisma gracillimum* (33 substitutions / 100% bootstrap) and the robust northern New Zealand plants (e.g. *E. robustum*9.06 and *E. robustum*9.01 (five substitutions / 100% bootstrap), but weak support for *E. minus* (1 substitution / 63% bootstrap).

We distinguished six distinct cpDNA haplotypes within the three species of *Empodisma*. Each accession of *E. gracillimum* was distinguished by one or more substitutions and constituted three unique haplotypes. The two sequences of *E. minus* from eastern Australia and Tasmania were identical and comprised the fourth haplotype (see also

Combined

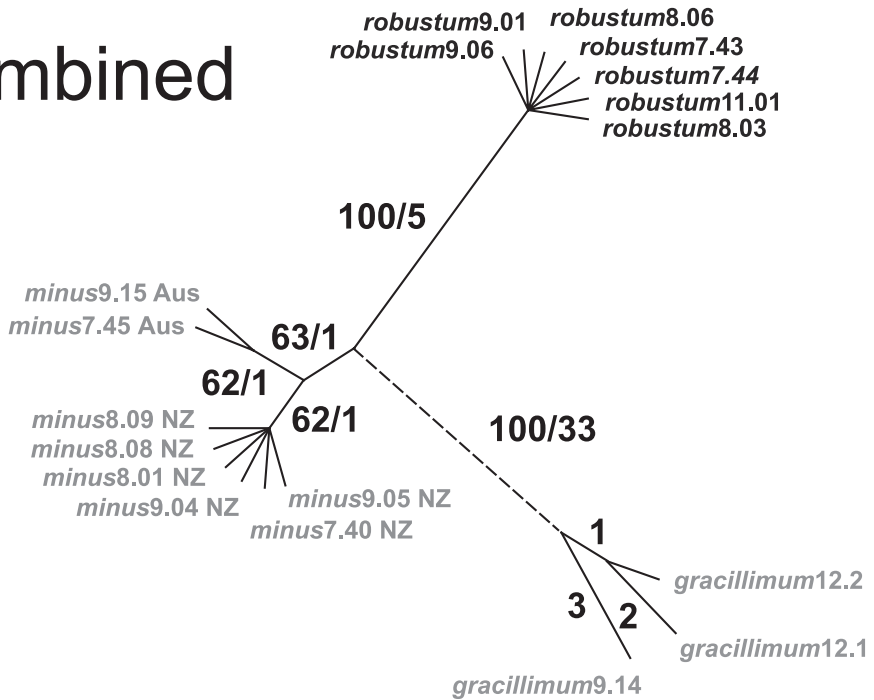

Figure 5. Unrooted parsimony tree from a combined analysis of the three sequence partitions. Six distinct cpDNA haplotypes are supported. Bootstrap values / the number of mutations distinguishing each haplotype are shown beside the branches. The accessions of *Empodisma minus* from New Zealand are indicated NZ and Australia Aus.

Figure 1). These were distinguished from a fifth haplotype comprising the *E. minus* accessions from New Zealand ranging from Stewart Island to approximately 38° S latitude on the North Island. The sequences of *E. robustum* restricted to the North Island of New Zealand north of 38° S latitude comprised a sixth haplotype.

We observed also a substantial degree phenotypic variation within the species of *Empodisma* especially in those characters that describe growth habit, e.g. culm height, internode distance, sheath length and leaf length. However, when grown together in common garden experiments in Hamilton, the two New Zealand species, *E. robustum* and *E. minus*, retained their distinctive growth forms, which suggests there is a genetic component to the pattern of morphological variation.

Empodisma robustum is generally a larger more robust plant, which ranges in height from 0.4 to over 1.3 m even taller in supporting vegetation, whereas *E. minus* approaches 0.8 m in lowland bogs in Queensland, but in southern latitudes and alpine environments the plants are dwarfed, barely reaching 0.3 m (Fig. 6). *Empodisma gracillimum* is similar in height to *E. robustum*, but the culms are light green in colour and more delicate; usually they are less than 0.7 mm in diameter. The culms of *E. robustum* are dark green and broader, in some individuals approaching 2.2 mm in diameter.

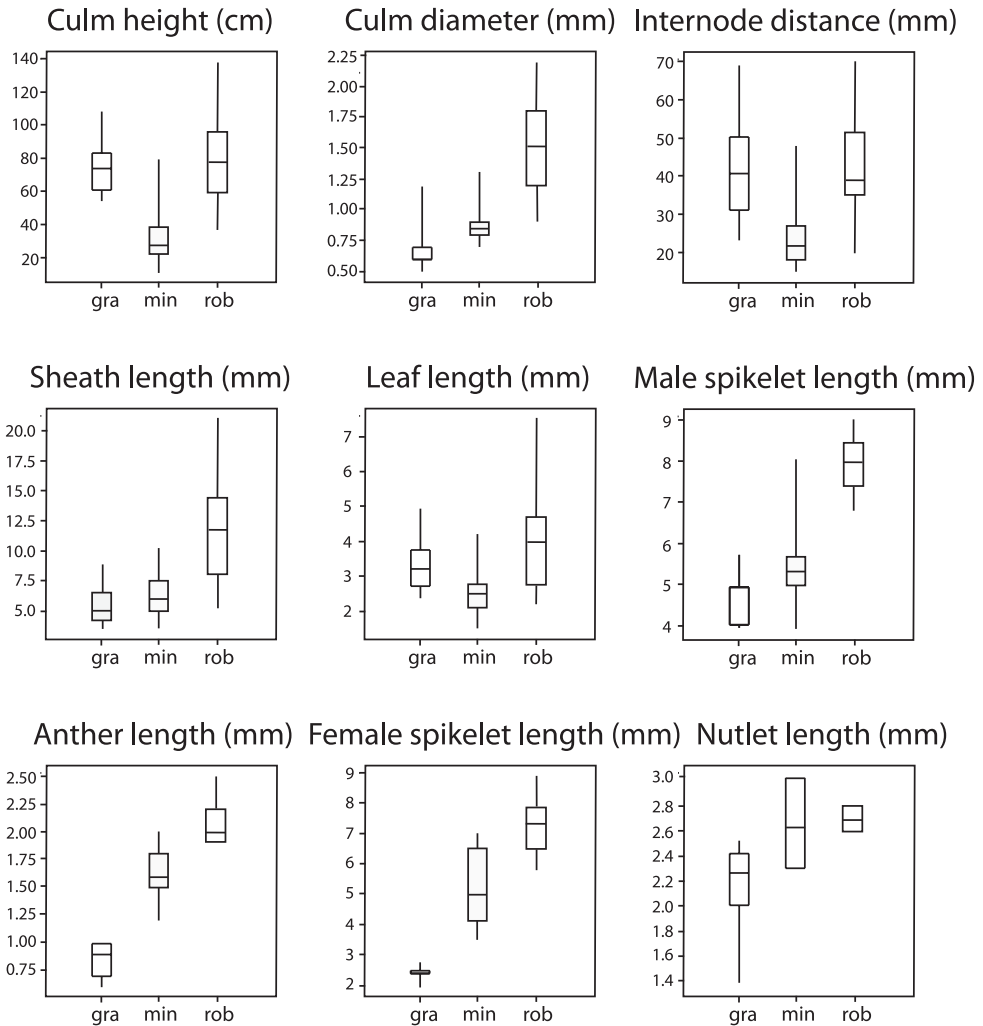

Figure 6. Box plots illustrating patterns of morphological variation among the species of *Empodisma*. The box spans the interquartile range of the values in the variate. The middle 50% of the data lie within the box, with a line showing the median. The whiskers extend beyond the ends of the box as far as the minimum and maximum values.

The culms of *E. minus* are also dark green, but they are seldom greater than 1.0 mm in diameter. Internode distances also vary substantially among the three species; the distances are greater in *E. robustum* and *E. gracillimum* ranging from 20.0 to 70.0 mm in *E. robustum* and from 25.0 to 80.0 in *E. gracillimum* in contrast to *E. minus* which ranges from 15.0 to 48.0 mm (Fig. 6). The leaf sheaths of *E. robustum* also tend to be longer, ranging from 5.2 to 21.0 mm, whereas the leaf sheaths of *E. gracillimum* range from 3.5 to 9.3 mm in length and from 3.5 to 10.2 mm in *E. minus*. The leaves of *E. robustum* are also longer, ranging from 2.2 to 7.55 mm, while the leaves range in length

from 2.4 to 5.0 mm in *E. gracillimum* and from 1.5 to 4.2 mm in *E. minus*. The floral structures of *E. robustum* are substantially longer than those of *E. minus*. In contrast, the inflorescences of *E. gracillimum* are smaller and more delicate than either *E. robustum* or *E. minus* (Fig. 6). The male spikelet of *Empodisma robustum* ranges from 6.8 to 9.0 mm in length, whereas *E. minus* ranges from 3.9 to 8.0 mm and *E. gracillimum* from 4.0 to 5.8 mm. The anthers in *E. robustum* range from 1.9 to 2.5 mm in length, 1.2 to 2.0 in *E. minus*, and 0.6 to 1.0 mm in *E. gracillimum*. The female spikelets in *Empodisma robustum* range from 5.8 to 8.9 mm in length, 3.5 to 7.0 mm in *E. minus* and 1.5 to 2.4 mm in *E. gracillimum*. While few of the herbarium specimens that we examined had mature fruits, fruits from *E. robustum* ranged from 2.6 to 2.8 mm in length, 2.3 to 3.0 mm in *E. minus*, and 1.4 to 2.5 mm in *E. gracillimum*.

The first PCoA axis accounted for 52.4 % of the variation in our sample and the second 23.4% (Fig. 7). The PCoA ordination separated *Empodisma gracillimum* primarily on the second axis but there was some overlap among the outliers of *E. robustum* and *E. minus* on the first axis. The greatest spread among the OTU's was observed in *E. robustum* and *E. gracillimum*; this might reflect their taller more scrambling growth habit. With the exception of one outlier from Queensland, specimens of *E. minus* are more tightly grouped. Several of the specimens of *E. minus* were collected in the high mountains or in lowland bogs at more southerly latitudes. The stature of these plants may be more constrained by the harsh environments that they inhabit.

Discussion

DeQueiroz (2007) proposed a unified species concept based on the single common element of most contemporary species definitions. He suggested that species are separately evolving metapopulation lineages. A metapopulation is a series of connected populations. A lineage implies an ancestor–descendant relationship. Species have a number of emergent biological properties, but these often arise at different times during the speciation process, and taxonomists may place a different emphasis on the biological properties that are used to define species. Incipient species may occupy a new adaptive zone, but this frequently precedes reproductive isolation and fixed morphological differences. The lowland plants of *Empodisma* from northern New Zealand exhibit many of these emergent properties. We feel the evidence is sufficient to justify recognizing the northern New Zealand plants as a distinct species and propose the name *E. robustum* S.J.Wagstaff & B.R.Clarkson sp. nov., which reflects its robust stature.

There is considerable uncertainty associated with estimating divergence times in Restionaceae. The fossil calibrations rely entirely upon microfossils and their affinities to extant genera are not clear. The divergence estimates presented here will undoubtedly be refined as more complete fossils are discovered. Nonetheless our preliminary findings suggest that *Empodisma* evolved in Australia during the mid Oligocene / early Miocene between 28–16 mya (Fig. 3). This was a time of warm, equitable environmental conditions. Crisp and Cook (2007) suggest members of the Restionaceae may

Figure 7. Principal coordinates ordination depicting patterns of overall similarity among the 74 OTEs that comprised our morphological sample. The first PC axis accounted for 58.3% of the variation in our sample and the second PC axis accounted for 23.4% of the variation.

have at one time been more widely distributed in Australia, but a rapid succession of marine incursions, the onset of aridity and the origin of the Nullarbor Plain during the Miocene beginning about 13–14 mya created climatic and edaphic barriers that isolated lineages in the southwestern and southeastern sclerophyll biomes in Australia. The split between *Empodisma gracillimum* and *E. minus* (13–5 mya) roughly coincided with these environmental changes. Colonization and diversification in New Zealand occurred more recently and was perhaps induced by uplift of the Southern Alps during

the Pliocene and episodes of glaciation during the Pleistocene. The split between *E. minus* and *E. robustum* (4–0.8 mya) spans this time frame.

The sequencing results also differentiate the populations of *Empodisma robustum* from northern New Zealand from the Australian or New Zealand populations of *E. minus* (Fig. 1), and this split was independently supported by each of the chloroplast DNA regions that we surveyed (Fig. 4). *Empodisma robustum* comprises a distinct evolutionary lineage united by six synapomorphies (Fig. 5). In contrast, the plants from mainland Australia and Tasmania are very similar to the diminutive lowland plants of *E. minus* from southern New Zealand, each haplotype is distinguished only by a single mutation and the plants are found in similar habitats. The three genes that we sequenced were encoded in the chloroplast and are probably maternally inherited. Interestingly, there is no homoplasy in the data. Nonetheless, it is conceivable that the chloroplast gene tree is not compatible with the species tree. Gene convergence, introgression hybridization and/or incomplete lineage sorting could result in incompatible phylogenetic signals. A degree of reproductive isolation is necessary for these mutations to become fixed, which suggests *E. robustum* and *E. minus* have been reproductively isolated, perhaps since the Pleistocene. Within the northern haplotype, the sequences are identical. Although the sample is small, the absence of unique mutations (autapomorphies) suggests gene flow is unrestricted among the northern populations of *E. robustum*. Historical rates of gene flow have traditionally been estimated indirectly from the number of fixed alleles in subpopulations relative to the total population (Sork et al. 1999, Slatkin and Maddison 1981).

Contrary to the observations of Moore and Edgar (1970), our results show that in New Zealand the pattern of morphological variation in *Empodisma minus* is not continuous from low to high elevation; rather two morphologically distinct New Zealand species can be readily distinguished. This interpretation is based upon recent collections from throughout the range of the species. *Empodisma robustum* differs by its more robust growth habit. The stature of *E. minus* diminishes with increasing latitude and altitude. Though they have distinct haplotypes, the diminutive plants of *E. minus* from New Zealand are morphologically very similar to plants from Tasmania, though plants from 0.4 to 1 m tall are noted from eastern Australia. We examined a specimen from Queensland that was 0.8 m tall. The culm diameter of 0.8 mm placed it within the range of the New Zealand accessions, but this plant was an outlier in the PCoA ordination (Fig. 7).

Hooker (1859) stated that the New Zealand plants could be distinguished from the Australian plants by their more woolly sheaths with erect apices. After close inspection we felt this was a relatively minor morphological difference, and considering the low bootstrap support and the small amount of genetic divergence, we did not consider these differences worthy of taxonomic recognition. *Empodisma gracillimum* emerges as sister to *E. minus* and *E. robustum* and is separated by 36 unique nucleotide substitutions. With its delicate light green culms, unbranched multicellular hairs on the rhizome, and pedicellate female flowers, *E. gracillimum* is morphologically very distinct from *E. robustum* and *E. minus*.

The three species of *Empodisma* also have distinct ecological and distributional differences.

Ecology of *Empodisma robustum*

Empodisma robustum is restricted to the region north of 38° S latitude on the North Island of New Zealand. This phytogeographical boundary has long been recognized by New Zealand ecologists and marks the southernmost range of many species, most notably *Agathis australis*, but also bog associates such as *Sporadanthus ferrugineus* de Lange, Heenan & B.D.Clarkson, *Dianella haemata* Heenan & de Lange, *Dracophyllum lessonianum* A.Rich., *Anzybas carsei* (Cheeseman) D.L.Jones & M.A.Clem., and *Lycopodiella serpentina* (Kunze) B.Øllg. This region is the warmest in New Zealand and is rich in endemic species (McGlone 1985). The pre-European vegetation in this part of New Zealand consisted primarily of warm-temperate forests and restiad peatlands.

Empodisma robustum is a mid- to late-successional species of restiad raised bogs in the lowland zone of northern North Island (Clarkson et al. 2004b). In the oldest bogs it forms a dense layer of sprawling, intertwined wiry stems 1–1.8 m in height, overtopped by swards of the bamboo-like *Sporadanthus ferrugineus* (also Restionaceae) up to 2.5 m tall (de Lange et al. 1999). Other canopy associates include the heath shrubs *Leptospermum scoparium* J.R.Forst. & G.Forst., *Epacris pauciflora* A.Rich., and *Dracophyllum lessonianum*, the sedges *Baumea teretifolia* (R.Br.) Palla and *Schoenus brevifolius* R.Br., and the fern *Gleichenia dicarpa* R.Br. *Sphagnum cristatum* Hampe is also present, but does not thrive in the shade of the taller restiads. These bogs were initiated in the post-glacial period (after 14 000 years BP; Newnham et al. 1995, McGlone 2009), and typically formed extensive domes covering up to 15 000 ha, with peat 10–12 m deep (Cranwell 1939). However, widespread drainage and development into pasture in the early to mid-1900s has confined the *Sporadanthus*–*Empodisma robustum* association to three sites in the Waikato: Torehape, Kopuatai, and Moanatuatua (de Lange et al. 1999, Clarkson 2002). Elsewhere in the northern North Island, *E. robustum* occurs in fens and young restiad bogs (Johnson and Brooke 1989, Johnson and Gerbeaux 2004, Hodges and Rapson 2011), and gumland heaths (Clarkson et al. 2011). Apart from *S. ferrugineus*, the species associated in these younger/shallower peat systems are similar to those listed above.

Empodisma robustum is the key species in the fen–bog transition (Clarkson et al. 2004b, Hodges and Rapson 2011) during the development of restiad raised bogs north of 38° S latitude. It is tolerant of a wide environmental range, establishing early in relatively fertile fens (dominated by *Gleichenia dicarpa*, sedges and heath shrubs) to initiate raised-bog development, and persists in significant amounts in low-nutrient, late-successional phases. It is the main peat former, with its dense surface layer of cluster roots that have high water-holding capacity (Campbell 1964), high resistance to decay (Kuder et al. 1998), and similar base-exchange properties to *Sphagnum* (Agnew et al. 1993). The presence of an initial *E. robustum* phase has been shown to be a precursor to the establishment of *Sporadanthus ferrugineus*, which becomes the physiognomic dominant in late-successional restiad raised bogs (Clarkson et al. 2004a).

The development of raised bogs is constrained by a delicate water balance. They typically form in regions with moderate to high rainfall, cool summers, poor drainage,

and isolation from flowing water (McGlone 2009). The warm-climate northern North Island lowlands thus appear unsuitable for raised bogs, having frequent dry summers with extended water deficits and a negative annual water balance (McGlone 2009). However, bogs with dense *Empodisma robustum* canopies have much lower evaporation rates than other wetland plant communities (Thompson et al. 1999). This is likely due to the high water-use-efficiency properties of *E. robustum*, namely reducing water loss by physiological controls of stomatal opening, having reduced scale-like leaves, and a dense mulch of decay-resistant culms, which protects the thick water-retaining root matrix at the bog surface (Campbell and Williamson 1997).

Because the raised-bog surface is isolated from the influence of groundwater and surface runoff, plants receive their water and nutrients from rainfall. They typically have very low levels of plant nutrients, particularly of nitrogen and phosphorus (Damman 1978, Clarkson et al. 2005). It has been shown that *E. robustum* is able to co-exist with the less nutrient demanding late-successional species *Sporadanthus ferrugineus*, by occupying different root zones (Clarkson et al. 2009). *Empodisma robustum* forms a thick layer of cluster roots that overlie the deeper roots of *Sporadanthus ferrugineus*, allowing preferential access to dissolved nutrients in rainfall.

Despite their saturated substrates, naturally occurring fires have been well documented in New Zealand peatlands (Newnham et al. 1995, McGlone 2009), and the frequency of fires has increased dramatically in recent times owing to land clearance by Polynesians and more widely by European settlers. Clarkson (1997) studied recovery from fire in two restiad raised bogs characterised by *E. robustum* at Whangamarino and Moanatuatua in Waikato. The populations of *E. robustum* were eliminated by fire and had to re-establish from seed, taking 4 years to achieve dominance at the two sites. Some minor resprouting was observed in localised pockets at Whangamarino (R.M. Irving, pers. comm., 1993) but recovery after fire is mostly via seed. *Empodisma robustum* has an erect rhizome, and its roots spread horizontally just below the surface of the bog, so its root system is susceptible to fire damage. Those species with rhizomes that penetrated deeply into the substrate, e.g. sedges, resprouted rapidly after fire and dominated in the first few years post-fire, before the restiads resumed pre-fire height and cover (*E. robustum* within 6 years and, where present, *Sporadanthus ferrugineus* within 12 years).

Ecology of *Empodisma minus*

Empodisma minus in New Zealand is also a mid- to late-successional wetland species. It dominates fens, blanket bogs, raised bogs, and pakihi heaths in coastal to alpine areas between 38° S latitude in the North Island and 48° S on Stewart Island, being particularly common in Westland and Southland. It is absent from Chatham Island. The vegetation is typically a dense, springy carpet of *E. minus*, averaging 40 cm tall, associated with heath shrubs (*Leptospermum scoparium*, *Dracophyllum oliveri* Du Rietz, *D. prostratum* Kirk), sedges (*Baumea teretifolia*, *B. tenax* (Hook.f.) S.T.Blake), the ferns

Gleichenia dicarpa and *G. microphylla* R.Br., the tussock grass *Chionochloa rubra* Zotov, sundews (*Drosera* spp.), and *Sphagnum cristatum* moss.

Many of the ecological properties of *E. robustum* also apply to *E. minus*. For example, *E. minus* forms peat via its cluster roots, although these are smaller and less dense than in *E. robustum*. It is also a key species in the fen–bog transition, particularly *C. rubra*-dominated fens (Hodges and Rapson 2011), and is the major peat former, except in very wet areas favoured by *Sphagnum* mosses (Rigg 1962, Burrows and Dobson 1972, Mark and Smith 1975, Whinam and Kirkpatrick 1995).

Empodisma minus resprouts after fire (Timmins 1992, Johnson 2001), and has probably become more common at the expense of woody species, because of land-clearance fires (McGlone 2009). Studies in vegetation recovery after fire in the far south of New Zealand at Eweburn Bog (Timmins 1992) and Awarua Bog (Johnson 2001) first noted resprouting (and some seed establishment) a few months after fire, but recovery was extremely slow and *E. minus* cover was still increasing after 4.5 years at Eweburn and 10 years at Awarua. However, after 40 years there was little difference observed in the cover of *E. minus* in the burnt and unburnt areas in a south Westland mire (Merton 1986). The magnitude of vegetation damage (and hence recovery) is determined by the intensity of the fire, which is influenced by site conditions such as water table depth, fuel build-up and climate (Timmins 1992, Clarkson 1997). In cooler, wetter regions, e.g. southern South Island, fires are likely to be less intense than fires in the northern North Island, which may favour the sprouter recovery strategy over the seeder strategy.

In Australia, *Empodisma minus* occurs in all states apart from Western Australia and Northern Territory, being concentrated in south-eastern Australia. It grows in similar habitats to New Zealand, i.e. fens and bogs, and seasonally or permanently inundated heaths, swamps and stream margins (Campbell 1983, Meney and Pate 1999, Whinam and Hope 2005) from sea level to alpine areas. *Empodisma minus* is most abundant at higher elevations, e.g. eastern Victoria highlands, and in cooler, wetter climates, e.g. Tasmania. Common associates include heath shrubs (*Richea continentis* B.L.Burt, *Baeckea gunniana* Schauer, *Leptospermum lanigerum* Sol. ex Aiton) Sm., *Epacris* spp.), sedges (*Carex gaudichaudiana* Kunth, *Carpha alpina* R.Br.), ferns (*Gleichenia alpina* R.Br., *G. dicarpa*), restiads, e.g. *Baloskion australe* (R.Br.) B.G.Briggs & L.A.S.Johnson, the monocotyledonous herb *Astelia alpina* R.Br., and *Sphagnum cristatum* moss. In lowland zones on the Australian mainland, e.g. eastern Australia, the more arid climate is not conducive to the formation of extensive raised peat bogs characteristic of lowland New Zealand (Campbell 1995). Conditions are suitable for *Empodisma* root growth and peat accumulation only during the wet season (usually winter). Dry conditions during the remainder of the year check root production and accelerate decomposition, resulting in only shallow deposits of peat. Associates in these warmer areas include the grass tree *Xanthorrhoea fulva* (A.T.Lee) D.J.Bedford, and heath and heath-like shrubs including *Sprengelia sprengelioides* (R.Br.) Druce, *Persoonia virgata* R.Br. and *Boronia falcifolia* A.Cunn. ex Endl. Recovery of *Empodisma minus* after fire is rapid. In the Victoria highlands, abundant resprouted plants were noted within a few weeks

of being burnt (Walsh and McDougall 2004), with new shoots from basal resprouts being several centimetres long within a month (McDougall 2007). *Empodisma minus* cover had returned to prefire levels within two years of burning and had continued to increase considerably by 17 years post-fire (Wahren and Walsh 2000). However, recovery of community composition to pre-fire levels may take many years because competition from *Empodisma* may impede the establishment and growth of more fire-sensitive species such as *Richea continentis* and *Epacris* spp.

Ecology of *Empodisma gracillimum*

Empodisma gracillimum is endemic to Australia. It is restricted to the coastal plain from Perth southwards, and along the south coast from Augusta to Albany (Meney and Pate 1999). This region receives the greatest amount of rainfall in the Southwest Australian Floristic Region (Hopper and Gioia 2004). *Empodisma gracillimum* inhabits seasonally or permanently inundated swamps, woodlands and stream margins on nutrient poor, peat or sandy peat soils (Meney and Pate 1999). It is locally abundant, forming dense masses up to 1.5 m high, is often associated with *Beaufortia sparsa* R.Br., *Leptocarpus* sp., and *Baumea rubiginosa* (Sol. ex G.Forst.) Boeckeler, and is often surrounded by tall shrubs such as *Agonis linearifolia* (DC.) Sweet, *A. parviceps* Schauer, *Homalospermum firmum* Schauer, *Hakea linearis* R.Br., *Callistemon glaucus* Sweet, and the woodland species *Eucalyptus marginata* D.Don ex Sm. and *E. calophylla* Lindl. Flowering occurs in the spring and summer with a prolonged seed maturation of 10 to 12 months. The vegetation of the Southwest Australia Floristic region is subject to frequent fires, and *Empodisma gracillimum* employs a sprouter recovery strategy following a fire (Meney et al. 1997).

Conclusions

The three species of *Empodisma* form a well-supported clade. The clade diverged during the early Miocene, which was a period of equitable environmental conditions in Australia. A rapid succession of marine incursions, the onset of aridity in Australia, and origin of the Nullarbor Plain during the mid to late Miocene created barriers that isolated the southwest Australian endemic *E. gracillimum* from the southeastern Australian *E. minus*. Dispersal, colonization and speciation in New Zealand occurred more recently, coinciding with the uplift of the Southern Alps during the Pliocene and episodes of glaciation during the Pleistocene. Genetic, morphological and ecological evidence supports the separation of *Empodisma minus* into two species, *E. minus* and *E. robustum*. The split between *E. minus* and *E. robustum* is unambiguous and independently supported by the three cpDNA regions that we surveyed. *Empodisma robustum* is distinguished by six unique nucleotide substitutions and a 23-base duplication. It is a taller, more robust plant that is typically killed by fire and confined to lowland regions

north of 38° S, whereas *E. minus* is smaller, resprouts after fire, and occurs in alpine and lowland areas south of 38° S. The western Australian species *E. gracillimum* emerges as sister to *E. minus* and *E. robustum*. It is geographically isolated and can be readily distinguished by its fine light green culms, shorter leaf sheaths and pedicellate female flowers. This last character appears to be a distinctive feature of the species.

Taxonomy

Empodisma L.A.S.Johnson & D.F.Cutler

<http://species-id.net/wiki/Empodisma>

Type species. *Empodisma minus* (Hook.f.) L.A.S.Johnson & D.F.Cutler

Description. Perennial herbs forming dense tangled masses, dioecious. Rhizomes stout up to 8.0 mm diam., covered with light brown, imbricate, scale-like sheaths and very thick tufts of brown hairs. Roots crowded, densely covered with persistent root hairs. Culms evergreen, hollow, dark to light green, profusely branching. Lamina reduced, awl-shaped, persistent, light green when young maturing dark brown, strongly reflexed from the leaf sheath. Leaf sheaths open, but overlapping and closely appressed, borne at short intervals, straw-coloured early in the season maturing dark brown, mouth ciliate with a tuft of woolly white hairs. Spikelets unisexual, borne in ultimate branch systems produced in second or third year, sessile or on short pedicels. Glumes imbricate; bracteoles lacking. Perianth segments 6, narrowly ovate almost hyaline. Male spikelets with 1–6 flowers, sessile to shortly pedicellate. Stamens 3, exerted beyond the perianth segments; filaments uniform; anthers linear oblong, dorsifixed, 1-celled, dehiscence along longitudinal slits, straw-coloured. Female spikelets solitary, each spikelet with 1– rarely 2 – flowers sessile to pedicellate. Ovary 1-celled; style branches 2 or 3, filiform, deciduous. Ovule solitary, pendulous. Fruit 1-seeded nut, ovoid with a thick and swollen base. $2n = 24$. Fruit development is protracted with the seeds maturing in the following winter or early spring.

Key to species of *Empodisma*

- 1 Robust plants forming dense tangled thickets; culms > 1 mm in diameter at base of the plant; sheaths mostly >7.5 mm long; spikelets > 6.0 mm long..... *E. robustum*
- Slender and/or diminutive plants; culms mostly < 1 mm in diameter, sheaths mostly < 7.5 mm long; spikelets generally < 6.0 mm2.
- 2 Culms dark green, 18–80 cm in height (some plants rarely to 1.2 m in Eastern Australia); female spikelets sessile to shortly pedicellate.....2. *E. minus*
- Culms light green, 55–130 cm in height; spikelets borne on pedicels up to 20 mm long.....3. *E. gracillimum*

1. *Empodisma robustum* Wagstaff & B.R. Clarkson, sp. nov.

urn:lsid:ipni.org:names:77120446-1

http://species-id.net/wiki/Empodisma_robustum

Holotype. (Fig. 8) New Zealand, Waikato, Hoe-O-Tainui, R. Mason, N.T. Moar 6750, 6/12/1958, CHR11159.

Etymology. *robustum* describes the robust stature of *E. robustum*.

Description. Culms dark green, 38–139 cm in height (reportedly > 200 cm when supported by associated shrubs), 0.9–2.2 mm in diameter at the base, branching profusely. Leaf sheaths open, closely appressed, 5.2–21.0 mm in length, borne at intervals of 20.0–70.0 mm, light green to light brown early in the season maturing dark brown; mouth ciliate with a tuft of woolly white hairs. Lamina strongly reflexed from leaf sheath, 2.2–7.5 mm long, light green when young maturing dark brown. Spikelets brown; male spikelet 6.8–9.0 mm long, anthers 1.9–2.5 mm; female spikelet 5.8–8.9 mm; nutlets dark brown approximately 2.7 mm long. Flowering Aug.–Oct. See Figure 9.

Comments. Many herbarium specimens of *E. robustum* include only the upper portion of the plant. These specimens may be difficult to distinguish from the larger specimens of *E. minus*. Quality specimens should include a rhizome and the base of the culms, from which the distinguishing measurements are taken. Most collections of *E. robustum* are either sterile or male, and the few females generally lack mature fruits. A chromosome count of $2n=24$ was reported from plants collected at Moanatuatua Bog (Briggs 1966, Johnson and Cutler 1973).

The acronym for the University of Waikato herbarium was recently changed from WAI to WAIK. We cited the older WAI acronym which appeared on specimen labels that we studied.

Distribution. New Zealand endemic ranging from North Cape southwards to approximately 38° S latitude.

Habitat. *Empodisma robustum* is restricted to ombrotrophic raised peat bogs where it often coexists with *Sporadanthus ferrugineus*, fens and gumland heathland peats. Locally abundant, but populations becoming fragmented by intensive land use.

Conservation status. Widespread drainage and conversion to pasture has dramatically reduced the extent of raised peat bogs in Northland and Waikato. This unique ecosystem is severely fragmented and provides habitat for a number of rare plant species such as *Sporadanthus ferrugineus* (de Lange et al. 1999) and *Dianella haemata* (Heenan and de Lange 2007). However, *E. robustum* is still relatively common in shallower/younger peat systems, and probably does not yet qualify as a threatened species. We recommend that its conservation status be regularly reviewed.

Hooker (1853) described the new species *Calorophus minor* Hook.f. based upon Bidwell, Colenso and Lyall specimens. A specimen collected near Nelson by Bidwell, no. 84, K000441989, was chosen as the lectotype by Moore and Edgar (1970).

short intervals 15.0–48.0 mm; light green to light brown early in the season maturing dark brown; mouth ciliate with a prominent tuft of woolly white hairs in New Zealand specimens, sparse or lacking in Australian specimens. Lamina strongly reflexed from leaf sheath, 1.5–4.2 mm long, persistent light green when young maturing dark brown. Spikelets brown, male spikelet 3.9–8 mm long, anthers 1.2–2.0 mm long; female spikelet 3.5–7.0 mm long; nutlets dark brown approximately 2.6 mm long. $2n = 24$. Flowering Aug.–Apr. [Fig. 11; see also illustration in Meney and Pate (1999)].

Comments. Morphologically similar to small forms of *Empodisma robustum* distinguished by its smaller stature (though plants from 0.4 to 1 m tall are noted from eastern Australia), more delicate culms and smaller spikelets. Most collections are sterile or male, and the few females generally lack mature fruits. Chromosome counts of $2n=24$ were reported from plants collected from the NW slope of Mt. Ruapehu and three counts from NSW (Briggs 1966, Johnson and Cutler 1973).

Harbond 20 Nov 1968, CHR183615.

Distribution. Widely distributed in Tasmania and all mainland Australian States except Western Australia and the Northern Territory; in New Zealand extending north to approximately 38°S latitude.

Habitat. Locally abundant in seasonally or permanently inundated wetlands, heathlands, fens and peat bogs from sea level to alpine

Conservation status. Not threatened.

3. *Empodisma gracillimum* (F.Muell.) L.A.S. Johnson & D.F.Cutler Kew Bull. 28: 383 (1973)

http://species-id.net/wiki/Empodisma_gracillimum

- ≡ *Calorophus gracillimus* F. Muell., *Fragm. Phytogr. Australiae* 8, 88 (1872–74) as ‘*Calostrophus*’
 ≡ *Hypolaena gracillima* (F.Muell.) Benth., *Fl. Austral.* 7, 239 (1878).

Syntypes. (Fig. 12; *vide* BG Briggs xi.1998), Nouvelle-Hollande, Riv. des cygnes, Preiss JA 1711, 1843. P00748711; Nouvelle-Hollande, Riv. des cygnes, Preiss JA 1714, 1843. P00748712.

Etymology. *gracillimum* describes the slender culms of *Empodisma gracillimum*.

Description. (illustrated in Menev and Pate 1999). Culms delicate light green, 55–110 cm in height, 0.5–1.2 mm in diameter, branching profusely. Leaf sheaths, open, closely appressed, 3.5–9.0 mm in length, borne at intervals 25.0–80.0 mm; lamina strongly reflexed from leaf sheath, 2.4–5.0 mm, persistent, light green when young becoming straw coloured. Spikelets light brown, male spikelet 4–5.8 mm, anthers 0.6–1.0 mm long; female spikelet 1.5–2.4 long mm borne on pedicels up to 20 mm long; nutlets approximately 1.4–2.5 mm long straw-coloured. $2n = 24$. Flowering Aug.–Apr.

Comments. Though it approaches *Empodisma robustum* in height, *E. gracillimum* is readily distinguished by its more delicate light green culms and shorter leaf sheaths. The male and female spikelets of *Empodisma gracillimum* are smaller than either *E. robustum* or *E. minus*. The female spikelets are solitary and distinctly pedicillate; this character may be a synapomorphy for the species.

Representative specimens. Western Australia, Denmark, ♂ and ♀ flowers, B.G. Briggs 8449 & L.A.S. Johnson, CHR525963; Western Australia, 4.4 km east Watershed Road, ♂ flowers, A.R. Annel, R.W. Figure 12. High resolution photograph of a syntype of *Empodisma gracillimum* (F. Muell.) L.A.S. Johnson & D.F. Cutler. Mueller (1872–74) originally described the plant as *Calorophus gracillimus* F. Muell. The specimen, Nouvelle-Hollande, Riv. des cygnes, Preiss JA 1711, 1843, P00748711 is held at HERBARIUM MUSEI PARIENSIS. The syntype was designated by BG Briggs xi.1998.

cliff, ♂ flowers, G.J. Keighery 16277, PERTH06330266; Western Australia, NE of Albany, E.M. Sandiford & D.A. Rathbone 1372, PERTH07926855.

Distribution. Endemic to western Australia on the coastal plain south of Perth extending along the south coast from Augusta to Albany.

Habitat. Grows on peat or sandy nutrient-poor soils. Locally abundant in seasonally or permanently inundated wetlands, swamps and stream margins.

Acknowledgements

We thank the curators of the Western Australia Herbarium (PERTH), Auckland Museum (AK), Te Papa-The National Museum of New Zealand (WELT), Waikato University Herbarium (WAIK) and Allan Herbarium (CHR) for the assistance with loans. The type of *Empodisma minus* was reproduced with the consent of the Royal Botanic Gardens, Kew, © The Board of Trustees of the Royal Botanic Gardens and *E. gracilimum* the Muséum National d'Histoire Naturelle (MNHN). Rebecca Wagstaff provided the beautifully rendered illustrations of *Empodisma minus* and *E. robustum*. Scott Bartlam and Jane Cruickshank helped with field and technical assistance. Earlier versions of this manuscript benefited greatly from the constructive suggestions provided by Ilse Breitwieser, David Glenny, Peter Heenan, Peter Linder and an anonymous reviewer. We would also like to acknowledge the careful editing of Christine Bezar and Anne Austin. This research was supported by the Ministry of Science and Innovation through the *Defining New Zealand's Land Biota* and the *Restoring Wetlands* contracts.
