Abstract

Objective—Increased plasma concentrations of the endogenous nitric oxide (NO) synthase inhibitor, asymmetric dimethylarginine (ADMA), decreased arginine bioavailability, and mitochondrial dysfunction have been reported in adult sepsis. We studied whether ADMA, arginine, and carnitine metabolism (a measure of mitochondrial dysfunction) are altered in pediatric sepsis and whether these are clinically useful biomarkers.

Design—Prospective, observational study

Setting—Pediatric intensive care unit at an academic medical center

Patients—Ninety patients 18 years-old—30 with severe sepsis or septic shock compared with thirty age-matched febrile and thirty age-matched healthy controls.

Interventions—None.

Measurements and Main Results—Plasma ADMA and whole blood arginine, citrulline, ornithine, and acylcarnitine:free carnitine (AC:FC) ratio were measured daily for septic patients and once for controls using tandem mass spectrometry. Plasma ADMA concentration (median, IQR $\mu\text{mol/L}$) on day 1 was lower in severe sepsis and septic shock (0.38, 0.30–0.56) compared

with febrile (0.45, 0.40–0.59) and healthy (0.60, 0.54–0.67) controls ($p < 0.001$), though decreased ADMA was predominantly found in neutropenic patients. Day 1 arginine was lower in septic (10, IQR 7–20 $\mu\text{mol/L}$) compared with healthy patients (32, IQR 23–40; $p < 0.001$), and the arginine:ornithine ratio was decreased in sepsis, indicating increased arginase activity (an alternative pathway for arginine metabolism). The arginine:ADMA and AC:FC ratios did not differ between septic and control patients. ADMA was inversely correlated with organ dysfunction by PELOD score ($r = -0.50$, $p = 0.009$), interleukin-6 ($r = -0.55$, $p = 0.01$), and interleukin-8 ($r = -0.52$, $p = 0.03$) on admission. Arginine, arginine:ADMA, and AC:FC were not associated with organ dysfunction or outcomes.

Conclusions—ADMA was decreased in pediatric sepsis and was inversely associated with inflammation and organ dysfunction. This suggests that inhibition of NO synthase by ADMA accumulation is unlikely to impact sepsis pathophysiology in septic children despite decreased arginine bioavailability. We did not find an association of ADMA with altered carnitine metabolism, nor were ADMA, arginine, and AC:FC useful as clinical biomarkers.

INTRODUCTION

The sepsis syndrome remains a major problem in pediatrics, with nearly 42,000 hospital admissions and \$2 billion in health care costs in the United States annually (1). To improve outcomes and target therapies in pediatric sepsis, we must better understand biochemical changes underlying the septic response, as well as developmental differences specific to children.

The nitric oxide (NO) pathway has long been recognized in the pathogenesis of sepsis, with effects on cardiovascular, immune, and mitochondrial function, though its precise role remains poorly understood (2). NO is synthesized from L-arginine by a family of NO synthase (NOS) isoforms (3). In sepsis, an up-regulation of inducible NOS leads to an increase in systemic NO production (2). However, attempts to inhibit NOS did not improve organ function and led to increased mortality (4–6). Moreover, decreased activity of constitutive NOS isoforms may cause areas of NO deficiency and contribute to endothelial, microcirculatory, and organ dysfunction (7). Blood arginine concentration and *de novo* arginine synthesis are also decreased in sepsis (8–10), which may further limit NO bioavailability (11).

Endogenous NOS inhibitors, such as asymmetric dimethylarginine (ADMA), may further influence NO availability in sepsis, and their importance has been increasingly recognized in disorders of endothelial dysfunction (12). ADMA is synthesized by methylation of arginine residues on proteins, released into circulation during protein turnover, and degraded by dimethylarginine dimethylaminohydrolase (DDAH) with renal and hepatic elimination (12). ADMA competitively inhibits all NOS isoforms and competes with arginine for intracellular transport via the γ -cationic transporter (12). Thus, accumulation of ADMA restricts NO synthesis and impairs NO-mediated endothelial and vascular function (13). In adults with sepsis and organ dysfunction, elevated plasma ADMA is associated with an increased risk of mortality (13–15). Furthermore, low arginine combined with elevated ADMA may additively limit NO production, and a low arginine:ADMA ratio has been linked to vascular dysfunction in rats (16) and adults with septic shock (13). However, there are no data on the role of ADMA in pediatric sepsis. We hypothesized that plasma ADMA would be increased

in children with sepsis and would be associated with severity of organ dysfunction, inflammation, and adverse outcomes.

ADMA has also been linked to mitochondrial dysfunction (17), an important mechanism of organ failure in sepsis (18). ADMA causes uncoupling of the NOS dimer, resulting in increased superoxide-mediated formation of peroxynitrite, nitration of mitochondrial proteins, and diminished ATP production (19, 20). In animal models, altered carnitine metabolism, specifically an elevated blood acylcarnitine:free carnitine (AC:FC) ratio, is reflective of intra-mitochondrial increases in the ratio of acyl-coenzyme A (acyl-CoA) to free CoA (21, 22). Alterations in these ratios are associated with decreased oxidative respiration and have been linked to impaired NO signaling (21). We therefore hypothesized that increased ADMA in pediatric sepsis would result in an elevated AC:FC ratio as a measure of mitochondrial dysfunction and would be associated with reduced NOS activity and greater organ dysfunction.

The objective of this study was to determine changes in plasma ADMA, arginine bioavailability, and carnitine metabolism in pediatric severe sepsis and septic shock, and to investigate the utility of ADMA, arginine, and AC:FC as potential biomarkers in pediatric sepsis.

MATERIALS AND METHODS

This prospective, observational study was performed in a 42-bed pediatric intensive care unit (PICU) at an academic medical center between May 2009 and December 2010. The study was approved by the local institutional review board and informed consent/assent was obtained.

Patient Population

Consecutively admitted patients to the PICU who were ≥ 18 years-old and met criteria for severe sepsis or septic shock as defined by the International Pediatric Consensus Conference (23) were eligible (septic patients). Exclusion criteria were cardiac arrest before admission, treatment with inhaled NO or sildenafil, supplementation with arginine, citrulline, or carnitine, a metabolic, urea cycle, or mitochondrial disorder, chronic renal or hepatic impairment, unrepaired cyanotic heart disease or single-ventricle anatomy, major surgery within the previous 72 hours, transfer from another facility with ongoing sepsis >24 hours, and prior study enrollment. Age-matched control patients from the same hospital were enrolled into two groups: 1) febrile (temperature $\geq 38.5^{\circ}\text{C}$) patients evaluated for infection without severe sepsis or shock (febrile controls) and 2) afebrile patients without evidence of an active infectious or inflammatory condition (e.g. patients undergoing endoscopy for chronic abdominal pain with normal results; healthy controls). Although various medical conditions have been reported to affect plasma ADMA levels, only disorders also listed for septic patients (e.g. chronic kidney injury) were used to exclude controls.

Data Collection

Clinical data were abstracted from the medical record onto a standardized form, and included comorbid conditions, source of infection, routine laboratory results, daily maximum inotrope score (IS) (24), mechanical ventilation, length of stay (LOS), nutritional source, and vital status. Organ dysfunction was classified using consensus criteria (23) and monitored for 28 days. Pediatric Index of Mortality (PIM)-2 score (25) and daily Pediatric Logistic Organ Dysfunction (dPELOD) scores (26) were calculated. To determine the association of ADMA with recovery from inotrope-dependent shock, septic patients were

classified as having “rapid recovery” if IS was ≤ 5 or “slow recovery” if IS remained > 5 on day 3 or later.

Study Measurements

For septic patients, blood was collected within 24 hours of admission (day 1), and then daily for seven days or PICU discharge, whichever came first, for measurement of ADMA, NO pathway intermediates (arginine and citrulline), ornithine, and carnitine profile. Arginine is the amino acid substrate for NOS, citrulline is produced in a stoichiometric 1:1 relationship with NO, and ornithine is the byproduct of arginine metabolism by the enzyme arginase. Interleukin (IL)-6, IL-8, and C-reactive protein (CRP) were measured as markers of inflammation. Brain natriuretic peptide (BNP) was measured as a marker of cardiac dysfunction. If consent could not be obtained within 24 hours of admission, study labs were measured on discarded blood from the earliest clinical samples drawn on day 1. Due to limited availability of discarded blood and the requirement that blood draws be timed with clinical sampling, not all study labs were measured on every day. If renal replacement therapy was initiated, no further blood was collected since hemodialysis lowers plasma ADMA concentration (27). For control patients, a single measurement of ADMA, arginine, citrulline, ornithine, and carnitine profile was performed.

Blood specimens were processed upon collection in the main hospital laboratory. CRP and BNP were measured in plasma using a Beckman DxC600 and Siemens Centaur analyzer, respectively. Remaining samples were then stored at -70°C for batched analysis. Plasma ADMA was measured by tandem mass spectrometry (LC-MS/MS) as previously described (28), except that ADMA- d_7 was incorporated as the internal standard, sample supernatant was dried to completion and reconstituted in mobile phase, and a Phenomenex Luna Silica column was used. From serum, IL-6 was measured using an enzyme-linked immunosorbent assay (R&D Systems, Minneapolis, MN), and IL-8 using an electrochemiluminescent detection system (Meso-Scale Discovery, Gaithersburg, MD). Whole blood for arginine, citrulline, ornithine, AC, and FC was collected on filter paper, dried and stored at -70°C , and measured by LC-MS/MS (29). Acylcarnitine values were combined sum of short, medium, and long chain AC groups, and the AC: FC ratio was calculated as previously described (22).

Outcome Measures

The primary outcome was the difference in plasma ADMA concentration between septic patients and febrile and healthy controls. Sample size calculation based on two studies of plasma ADMA in critically ill adults (14, 15) determined that 30 septic patients, 30 febrile controls, and 30 healthy controls were needed to detect a difference in ADMA of $0.3 \mu\text{mol/L}$ with an alpha of 0.05 and 80% power. Secondary outcomes were differences in NO pathway intermediates and AC:FC between groups and the association of ADMA, arginine, and AC:FC with measures of organ dysfunction, inflammation, and clinical outcome. Three ratios were also analyzed—arginine:ADMA as a marker of arginine availability to NOS (13), citrulline:arginine as a surrogate for NOS activity (30), and arginine:ornithine as a measure of arginase activity (31).

Statistical Analysis

Statistical analysis was performed using Statistical Package for the Social Sciences (SPSS Version 12.1, Chicago, IL) and SAS 9.2 (SAS institute Inc., Cary, NC). Since data were not normally distributed, we reported medians with interquartile range (IQR) and used Wilcoxon rank-sum or Kruskal-Wallis tests to compare continuous and chi-square or Fisher's exact test for dichotomous variables. Longitudinal changes of repeated measurements in septic patients were analyzed using linear mixed modeling with a random

intercept. Associations of ADMA, arginine, arginine:ADMA, and AC:FC with measures of organ dysfunction, inflammation, and outcome were tested using Spearman's coefficient (r_s) with Bonferroni correction for multiple comparisons. The area under the receiver operating characteristic (AUROC) curve determined the utility of ADMA to differentiate septic children from febrile controls and septic patients with rapid versus slow recovery. A *post-hoc* analysis of patients with neutropenia (absolute neutrophil count < 500 thous/ μ L) was performed after an association of ADMA with white blood cell count (WBC) was observed using two-way ANOVA. P-values ≤ 0.05 were considered significant.

RESULTS

Of the 1789 patients consecutively admitted to the PICU, 85 (4.8%) met criteria for severe sepsis or septic shock. Thirty-seven of these patients were excluded, with 30 (63%) of the remaining 48 eligible septic patients consenting to enrollment (Figure 1). Thirty age-matched febrile and 30 age-matched healthy control patients were also enrolled. Patient characteristics are shown in Table 1. There was no difference in age, gender, or ethnicity between groups. Septic patients had higher PIM-2 and PELOD scores and a longer hospital LOS (all $p < 0.001$).

ADMA, NO pathway intermediates, and arginine:ADMA ratio

The plasma ADMA concentration (median, IQR μ mol/L) on day 1 was lower in septic patients (0.38, 0.30–0.56) compared with febrile (0.45, 0.40–0.59) and healthy (0.60, 0.54–0.67) controls ($p < 0.001$; Table 2). Arginine and citrulline on day 1 were also significantly different across the three groups (Table 2). However, arginine and citrulline (median, IQR μ mol/L) were only lower in septic patients (arginine: 10, 7–20; citrulline: 8, 4–10) compared with healthy controls (arginine: 32, 23–40; citrulline: 16, 13–19; both $p < 0.001$); there was no difference compared with febrile controls (both $p > 0.05$).

There was no difference between groups in the day 1 arginine:ADMA or citrulline:arginine ratios, though septic patients had a lower arginine:ornithine ratio than febrile and healthy control patients ($p = 0.03$), suggesting increased arginase activity in septic patients (Table 2). Day 2 results for septic patients were also compared with control groups and yielded similar results (Table 2). Plasma ADMA increased over the study period in septic patients ($p < 0.0001$), but there were no significant changes in arginine, arginine:ADMA, or arginine:ornithine (Figure 2) or citrulline:arginine ($p = 0.90$) over time.

As an indirect measure of the effects of ADMA on NOS activity, we examined the relationship with ADMA levels and citrulline:arginine ratio. There was a non-significant inverse relationship between plasma ADMA and citrulline:arginine ratio for septic patients on day 1 ($r_s = -0.32$, $p = 0.31$). A similar trend was noted on days 3 through 6 with significance reached on day 4 ($p = 0.03$), though this became non-significant after correction for multiple comparisons. For both febrile and healthy controls, no association was observed between ADMA and citrulline:arginine (both $p > 0.05$).

There was a significant interaction between ADMA and WBC ($p = 0.01$, two-way ANOVA). In the 13 septic patients who presented with neutropenia, all of whom had known malignancies, the plasma ADMA concentration (median, IQR μ mol/L) on day 1 (0.30, 0.27–0.36) was lower than in the septic patients without neutropenia (0.51, 0.39–0.63; $p < 0.001$) and remained lower through day 4. When neutropenic patients were excluded, day 1 ADMA in the septic patients did not differ from febrile controls ($p = 0.67$) but remained lower than healthy controls ($p = 0.04$). Although red blood cells may provide an important source for circulating ADMA (32) and could serve as a reservoir in non-neutropenic patients less likely to have concurrent anemia, ADMA was not correlated with hemoglobin in either septic

($r=0.09$, $p=0.65$) or febrile patients ($r=-0.28$, $p=0.14$; no data for healthy controls). Further comparisons between septic patients with and without neutropenia are shown in Table 3.

Other than higher arginine levels in septic patients receiving enteral nutrition on day 2 (enteral: 33, IQR 9–46; parenteral: 10, IQR 8–14; none: 9, IQR 7–21 $\mu\text{mol/L}$; $p=0.04$) and day 3 ($p=0.07$), there was no effect of nutrition on ADMA, arginine, or arginine:ADMA.

ADMA, arginine, and arginine:ADMA as clinical biomarkers

The AUROC curve for ADMA to differentiate between septic and febrile patients was 0.65 (95% CI 0.50–0.80). The ADMA cut-point of 0.50 $\mu\text{mol/L}$ yielded a sensitivity of 69% (95% CI 56, 81%), specificity of 37% (95% CI 24, 47%), positive-predictive value of 49% (95% CI 40, 57%), and negative-predictive value of 58% (95% CI 40, 75%) to diagnose sepsis.

In septic patients, day 1 plasma ADMA concentration was inversely associated with day 1 PELOD score ($r_s=-0.50$, $p=0.009$), IL-6 ($r_s=-0.55$, $p=0.01$), and IL-8 ($r_s=-0.52$, $p=0.03$) and was directly associated with WBC ($r_s=0.76$, $p=0.001$). A significant association between daily ADMA and WBC was also found through study day 4 (data not shown). Day 1 plasma ADMA was not correlated with age, PIM-2 score, IS, hepatic or renal function, BNP, lactate, CRP, LOS, or inotrope- or ventilator-free days (Table 4). Neither arginine nor arginine:ADMA on day 1 were associated with measures of organ dysfunction, inflammation, or clinical outcomes (Table 4). After correction for multiple comparisons in Table 4, only the association between ADMA and WBC remained significant at the $p<0.003$ level. The rise in ADMA observed in septic patients over study period was not associated with changes in dPELOD, CRP, IL-6, IL-8, IS, LOS, or inotrope- or ventilator-free days (all $p>0.05$). There were no differences between the 11 (37%) septic patients with a rapid versus those with a slow recovery from hemodynamic support with vasoactive infusions for day 1 ADMA (median 0.33, IQR 0.29–0.45 vs 0.41, 0.35–0.59 $\mu\text{mol/L}$; $p=0.24$), day 2 ADMA (0.44, 0.33–0.56 vs 0.43, 0.36–0.56 $\mu\text{mol/L}$; $p=0.93$), or change in ADMA over time ($p>0.05$). Similarly, there were no differences between septic patients with rapid versus slow recovery for day 1 or day 2 arginine, arginine:ADMA, or arginine:ornithine (all $p>0.05$). However, there was a trend towards a decrease in both the arginine concentration and arginine:ADMA ratio in septic patients with ongoing need for vasoactive infusions on day 3 and a corresponding increase in the citrulline:arginine ratio (Figure 3). For prediction of rapid recovery, the AUROC curve for ADMA on day 1 was 0.68 (95% CI 0.45, 0.90).

ADMA and carnitine metabolism

There were no differences in the AC:FC ratio, as a measure of mitochondrial dysfunction, on day 1 between septic patients and febrile and healthy controls (Table 2). Septic patients in the highest ADMA quartile did have a higher median AC:FC ratio on all study days compared to those in the lowest ADMA quartile, including day 1 (1.35, IQR 0.72–3.12 vs 0.44, IQR 0.41–2.16, $p=0.57$) and day 2 (1.80, IQR 0.82–2.7 vs 0.67, IQR 0.56–0.82, $p=0.15$); however, these differences did not reach significance. There was also no significant association of AC:FC with arginine:ADMA on any study day after correction for multiple comparisons. A trend towards an inverse association between AC:FC and citrulline:arginine was seen on day 1 ($r_s=-0.53$, $p=0.08$) and on all subsequent study days, with significance reached on study days 3 ($r_s=-0.50$, $p=0.01$) and 5 ($r_s=-0.71$, $p<0.001$). There was no association between the daily AC:FC ratio or changes in this ratio and dPELOD score ($p>0.05$ on all study days).

DISCUSSION

The principal findings of this study is that plasma ADMA, a key regulatory mechanism of NO homeostasis, is decreased and the arginine:ADMA ratio is unchanged in pediatric severe sepsis and septic shock. These findings contrast with studies of septic shock in adults, in which plasma ADMA was increased and arginine:ADMA was decreased (13–15). Similar to prior investigations, we found evidence for decreased arginine bioavailability, including lower blood arginine levels and lower arginine:ornithine ratios (suggesting increased arginase activity) in septic children. Low initial plasma ADMA levels were associated with increased organ dysfunction and inflammation, although not with adverse outcomes. There was no association between changes in ADMA over time and organ dysfunction, or between ADMA and AC:FC as a measure of mitochondrial dysfunction.

Accumulation of ADMA inhibits NO-mediated vasodilatation, promotes platelet and leukocyte interactions with endothelial cells, and increases reactive oxygen species through uncoupling of the NOS dimer (17, 33). Increased ADMA has been proposed as an important mechanism of endothelial and vascular dysfunction in several disease states (28, 34–36). In critically ill adults, escalating plasma ADMA has been associated with increased mortality (14, 15). We hypothesized that a similar increase in plasma ADMA would occur in children with sepsis as a potential mechanism leading to organ dysfunction and adverse outcomes. In contrast, we found plasma ADMA to be decreased in pediatric sepsis with concurrent neutropenia and unchanged without neutropenia. In addition, despite previous studies showing ADMA to be decreased in moderate illness but increased with higher severity (13, 37), we observed a stepwise decline from healthy to febrile to septic patients indicating a “dose-response” decrease in ADMA with increasing illness severity. These findings suggest that inhibition of NO signaling through ADMA accumulation may be less likely to play a major role in the pathophysiology of sepsis in younger patients than has been postulated for adults (33).

Several important developmental differences could account for lower plasma ADMA levels in septic children compared with older patients, including decreased protein catabolism (less ADMA synthesis), reduced incidence of renal or hepatic dysfunction (enhanced ADMA clearance), and a lower rate of microangiopathic hemolysis (less red blood cell-related ADMA release). The presence of hepatic failure in particular has been suggested as a primary determinant of increased ADMA in septic adults (14, 33). Alternatively, the lower prevalence of pre-existing vascular pathology, such as hypertension and atherosclerosis, in younger patients may predispose to less ADMA accumulation (38). For example, plasma ADMA was unchanged after lipopolysaccharide (LPS) administration to “healthy young men” without preexisting cardiovascular disease (39). It is also possible that children with sepsis are better able to maintain ADMA homeostasis through a preserved feedback loop, whereby a decrease in NO leads to increased DDAH activity, faster metabolism of ADMA, and a subsequent increase in NOS activity (40). Thus, low plasma ADMA may reflect, rather than cause, decreased NO production in younger individuals.

Several physiological mechanisms may underlay the decrease in plasma ADMA observed in our septic patients. The acute inflammatory response characteristic of the early phase of sepsis may enhance DDAH activity and, thus, suppress ADMA levels. Although LPS and tumor necrosis factor- α appear to inhibit DDAH *in vitro* (40, 41), their effect *in vivo* remains unclear. While endotoxin decreased DDAH activity in a mouse model of acute lung injury (19), several clinical studies have shown plasma ADMA levels to be unchanged in the setting of acute inflammation (42), sepsis without shock (13), and moderate malaria (37), as well as reduced or unchanged following experimental administration of LPS (39, 43). In addition, our study is consistent with others demonstrating an inverse association of ADMA

with inflammatory markers (e.g. IL-6) and a rise in ADMA once the infectious/inflammatory process subsides (42, 44). Other potential explanations for the low ADMA concentrations include increased cellular uptake by the y⁺ transporter in sepsis (45), altered activity of the methyltransferase enzymes that produce ADMA, and decreased substrate availability (i.e. diminished arginine).

Impairment of arginine homeostasis can also impact NO signaling (46), and the low blood arginine and citrulline in this study is consistent with previous reports in sepsis (8–10). Decreased arginine stems primarily from diminished *de novo* synthesis from citrulline, increased consumption from up-regulation of inducible NOS and arginase (8, 9, 47), and enhanced uptake via the y⁺ transporter (45). Although we did not find a difference in the citrulline:arginine ratio to support increased NOS activity, we did find indirect evidence of increased arginase activity (decreased arginine:ornithine ratio). Furthermore, the net effect of altered arginine bioavailability on NOS synthesis may be better determined by the arginine:ADMA ratio (13). There was a trend toward a lower ratio in septic patients compared to healthy controls, and in those with slow versus rapid recovery, but these differences were not significant.

In vitro studies have shown that ADMA-induced uncoupling of the NOS dimer leads to a decrease in NO production with a concurrent increase in reactive oxygen species and protein nitration that contribute to mitochondrial dysfunction (17, 19, 20), an important mechanism for sepsis-related organ dysfunction. This process may be accelerated in the presence of arginine deficiency (17). An increase in blood AC:FC as a surrogate for increased intra-mitochondrial acyl-CoA:CoA and mitochondrial dysfunction has been shown in pre-clinical (22) and clinical studies (29). Alterations in carnitine metabolism have also been linked to impaired NO signaling (21). This potential linkage between ADMA-induced NOS uncoupling leading to increased superoxide, altered carnitine metabolism, and decreased mitochondrial function has not previously been studied in pediatric sepsis. Although we did not find a difference in carnitine metabolism between study groups, or an association of AC:FC with ADMA, there was a suggestion that increased AC:FC may be associated with decreased NOS activity on all study days. This may reflect a connection between NOS uncoupling and mitochondrial dysfunction and merits further study.

Ideally, measurement of plasma ADMA or arginine:ADMA ratio would serve as a clinically relevant biomarker for impaired endothelial, microvascular, and mitochondrial function and identify those septic patients at highest risk for multi-organ failure and poor outcomes. While day 1 ADMA was inversely associated with organ dysfunction and the inflammatory cytokines, IL-6 and IL-8, we did not find evidence to support measurement of initial ADMA, arginine, or AC:FC to predict adverse clinical outcomes. Despite its potential for regulating NO-mediated hemodynamic changes, neither the initial nor changes in ADMA were able to predict the degree of hemodynamic support or recovery from inotrope-dependent shock. However, we did observe a slight decrease in arginine:ADMA in septic patients with “slow recovery” from vasoactive infusion therapy suggesting that following changes in ADMA relative to arginine may have clinical utility in pediatric sepsis.

The strongest association we found between ADMA and the inflammatory response was with WBC, an unexpected finding. This led to a *post-hoc* analysis in which we found neutropenic patients with sepsis to have lower ADMA levels than non-neutropenic patients. In conjunction with previous studies (48), these findings suggest differential regulation of the NO pathway in neutropenia. Alternatively, the higher IL-6 and IL-8 concentrations observed in neutropenic patients may have led to greater suppression of ADMA if increased inflammation does enhance DDAH activity. Although there were no differences in PIM-2 score, IS, CRP, or inotrope- or ventilator-free days, the low levels of IL-6 and IL-8 may also

indicate a selectively reduced severity of illness in our non-neutropenic patients. Thus, these findings require further exploration in a larger, planned analysis.

There are several limitations to this study. Given the small sample size and lack of standardized treatment, differences in outcomes and the impact of nutrition could have been underestimated, and we cannot exclude the possibility that a subset of septic children may have increased ADMA. We also used the citrulline:arginine and arginine:ornithine ratios as surrogates for NOS and arginase activity, respectively. While a precedent exists (30, 31), these amino acids are not specific for a particular enzymatic reaction. Therefore, the absence of a strong inverse relationship between ADMA and citrulline:arginine in this study does not necessarily preclude an effect of altered ADMA on NO synthesis. Future studies incorporating measures of NO bioactivity are necessary to fully establish the effect of altered arginine and ADMA on NOS activity in pediatric sepsis. Finally, while the observed decrease in ADMA between groups was small, Cardounel et al. (49) has shown that changes in plasma ADMA of ~0.5 $\mu\text{mol/L}$ have large effects on intracellular NOS inhibition, supporting the physiological importance of even slight changes in circulating ADMA.

CONCLUSIONS

We found that plasma ADMA, in contrast to adult studies, was decreased in pediatric severe sepsis and septic shock (primarily with neutropenia), and that the arginine:ADMA ratio was unchanged. This suggests that, despite diminished arginine bioavailability, ADMA accumulation and inhibition of NOS may be less likely to play a prominent role in the pathophysiology of pediatric sepsis and sepsis-related organ and mitochondrial dysfunction. While we did not find ADMA, arginine, or AC:FC ratio to be clinically useful biomarkers, this study helps to define the natural history of ADMA and arginine metabolism in pediatric sepsis and highlights a potentially important developmental difference between pediatrics and adults.

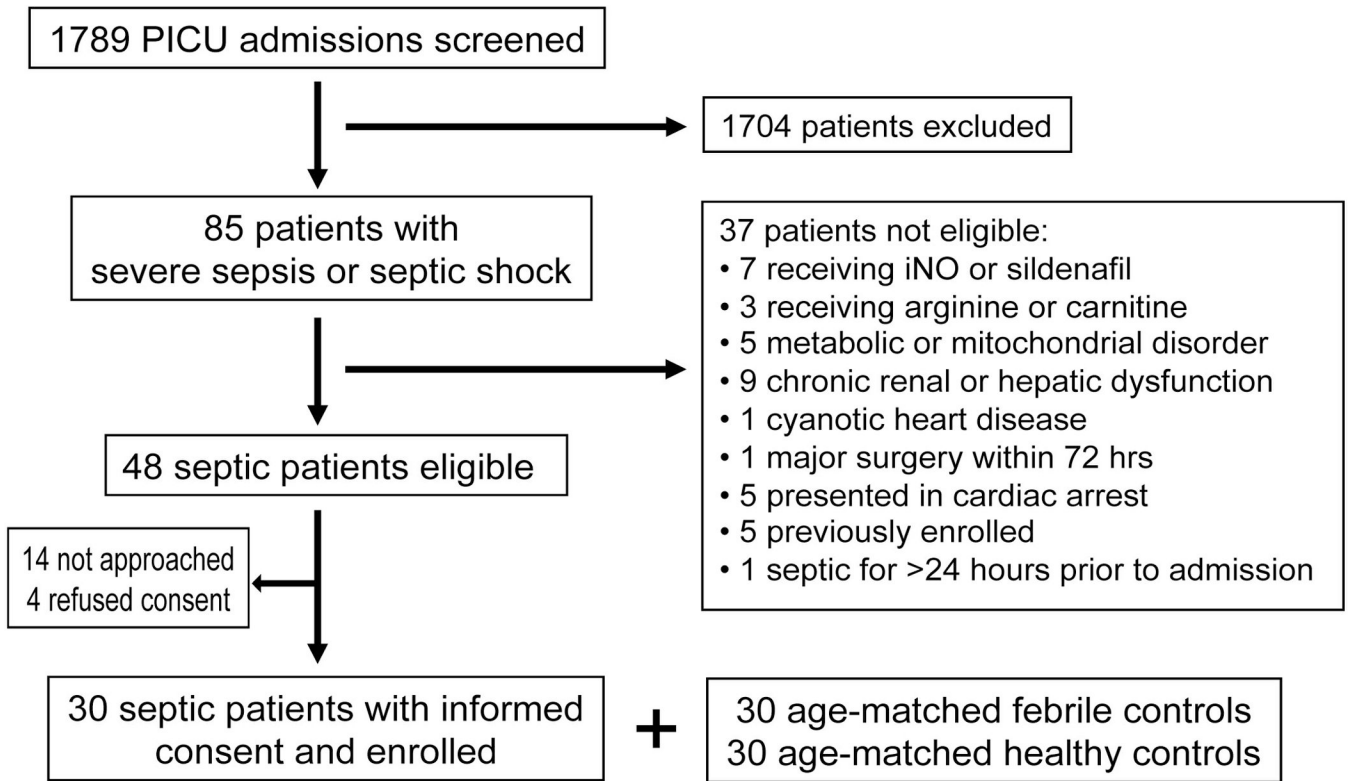

Figure 1.
Patient screening and study enrollment

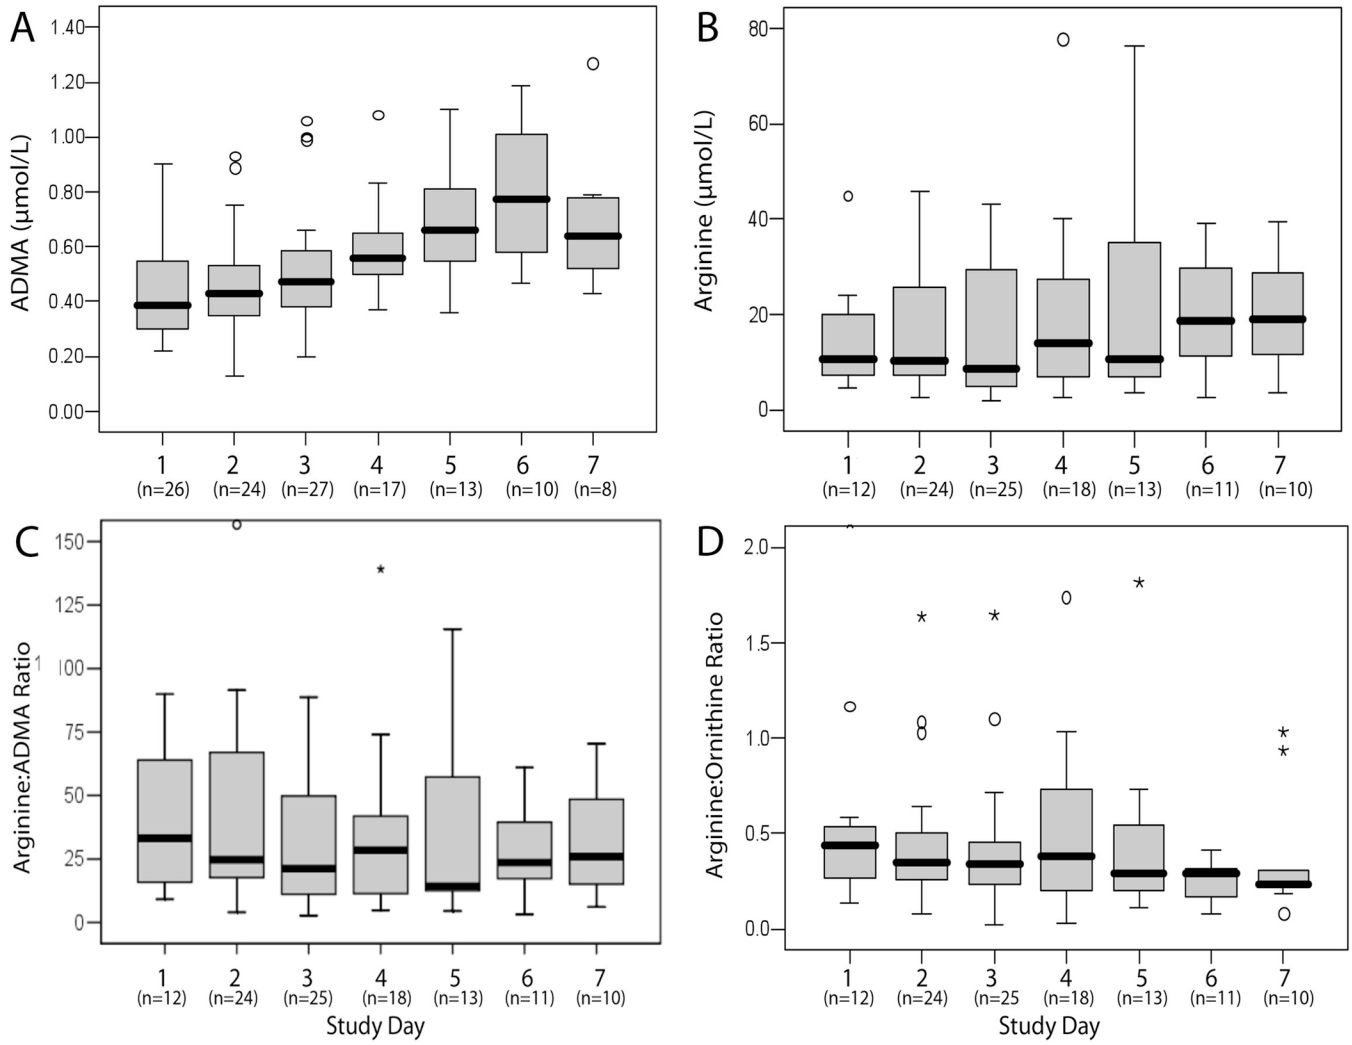

Figure 2. Longitudinal analysis in septic patients Data are presented in box-plot analysis with central line indicating the median and grey box indicating the interquartile range. Longitudinal changes over time for septic patients were significant for asymmetric dimethylarginine (A, $p < 0.0001$), but not for arginine (B, $p = 0.48$), arginine:ADMA ratio (C, $p = 0.96$), or arginine:ornithine ratio (D, $p = 0.82$).

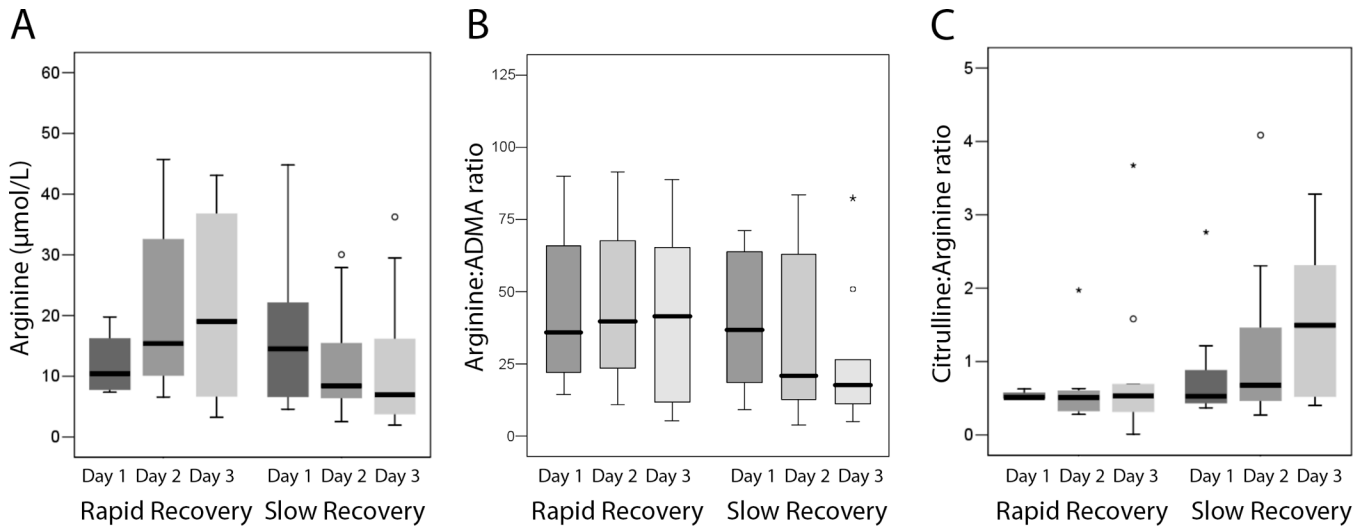

Figure 3.

Arginine concentrations and related ratios in septic patients with rapid versus slow recovery from hemodynamic support. A progressive decline in arginine concentration (A) and the arginine:ADMA ratio (B) and an increase in the citrulline:arginine ratio (C) were observed for septic patients with an inotrope score (IS) > 5 on day 3 (“slow recovery”) compared with septic patients with IS ≤ 5 on day 3 (“rapid recovery”); however the differences on day 3 did not reach significance for arginine (p=0.17), arginine:ADMA (p=0.28), or citrulline:arginine (p=0.07).

Table 1

Patient characteristics^a

Characteristic	Septic n = 30	Febrile Controls n = 30	Healthy Controls n = 30
Age (years)	7.2 (2.4–15.4)	9.2 (1.8–15.7)	8.2 (3.5–14.6)
Gender, % male	50	40	70
Ethnicity, n (%)			
White, non-hispanic	9 (30)	8 (27)	17 (57)
Black	6 (20)	6 (20)	4 (13)
Hispanic	14 (47)	13 (43)	5 (17)
