Effects of combined antiretroviral therapy on B- and T-cell release from production sites in long-term treated HIV-1⁺ patients

Eugenia Quiros-Roldan¹, Federico Serana², Marco Chiarini², Cinzia Zanotti², Alessandra Sottini², Daria Gotti¹, Carlo Torti¹, Luigi Caimi² and Luisa Imberti^{2*}

Abstract

Background: The immune system reconstitution in HIV-1- infected patients undergoing combined antiretroviral therapy is routinely evaluated by T-cell phenotyping, even though the infection also impairs the B-cell mediated immunity. To find new laboratory markers of therapy effectiveness, both B- and T- immune recovery were evaluated by means of a follow-up study of long-term treated HIV-1- infected patients, with a special focus on the measure of new B- and T-lymphocyte production.

Methods: A longitudinal analysis was performed in samples obtained from HIV-1-infected patients before therapy beginning and after 6, 12, and 72 months with a duplex real-time PCR allowing the detection of K-deleting recombination excision circles (KRECs) and T-cell receptor excision circles (TRECs), as measures of bone-marrow and thymic output, respectively. A cross sectional analysis was performed to detect B- and T-cell subsets by flow cytometry in samples obtained at the end of the follow-up, which were compared to those of untreated HIV-1-infected patients and uninfected controls.

Results: The kinetics and the timings of B- and T-cell release from the bone marrow and thymus during antiretroviral therapy were substantially different, with a decreased B-cell release and an increased thymic output after the prolonged therapy. The multivariable regression analysis showed that a longer pre-therapy infection duration predicts a minor TREC increase and a major KREC reduction.

Conclusions: The quantification of KRECs and TRECs represents an improved method to monitor the effects of therapies capable of influencing the immune cell pool composition in HIV-1-infected patients.

Keywords: KRECs, TRECs, HIV-1, cART, T lymphocytes, B lymphocytes

Background

Although CD4⁺ T cells are the major target of HIV-1, this infection widely impairs the viability and function of numerous other immune cells [1]. In particular, in the absence of therapy, HIV-1 infection is associated with several B-cell defects, including polyclonal hypergammaglobulinemia [2], modified expression of activation and costimulatory markers [3-6], decreased B-cell survival [7,8], and the presence of exhausted terminally differentiated B cells or CD27⁺ memory B cells [9-11].

Furthermore, recent results showed that HIV-1 infection not only induces a strong depletion in memory B cells, but is also associated with defects in the naive B-cell subset [12].

Combined antiretroviral therapy (cART) is very efficient in reducing HIV-1 load and, currently, even with salvage therapy, up to 90% of treated HIV-1-infected adults attain viral RNA plasma levels under the limit of detection of commercially available tests [13]. As a consequence of the viral suppression, resulting into a gradual reprise of thymic output, the CD4⁺ cell count reaches normal levels in most but not all treated patients [14]. Still, in some of them, the T-cell recovery remains abnormally low in spite of the complete suppression of

viral replication, and they are at increased risk of disease progression and death [15-17]. Therefore, one of the problems in the field of anti-viral therapy in HIV-1-infected patients is how to achieve an efficient monitoring of the immune reconstitution following cART. Routinely, the immune system restoration is evaluated by T-cell phenotyping. A more specific way to measure the recovery of the immune system is the quantification of the recent thymic emigrants (RTE) that are CD4⁺ lymphocytes expressing the CD45RA and CD31 markers or harbouring the T-cell receptor excision circles (TRECs), which are extrachromosomal circular DNA episomes produced during T-cell receptor rearrangement. TRECs, in particular, have been used as a surrogate marker of thymic output [18]. While TREC number in HIV-1-infected patients has been found to correlate with different clinical-pathological parameters (age, plasma HIV-1 RNA, CD4⁺ T-lymphocyte counts, CD4⁺ T-lymphocyte percentages, and naive CD4⁺ T-lymphocyte number) and TREC number of HIV-1-infected children increases during cART [19-22], to our knowledge, no studies have investigated the effects of cART treatment on the release of new B lymphocytes from the bone marrow of treated patients. Moreover, it is not known whether the recovery of B and T cells occurs simultaneously. Therefore, here, the effect of cART on the mobilization of new B and T cells during a long follow-up (72 months) was analyzed by a duplex real-time PCR that combines the measure of TRECs with the quantification of the "K deleting recombination excision circles" (KRECs) that assesses the extent of the B-cell output [23,24]. Real-time PCR was also used to quantify the mRNA expression of interleukin 7 (IL-7) and of the alpha chain of IL-7 receptor (IL-7R α), while flow cytometry was used to evaluate the cell surface expression of IL-7R α on CD4⁺ cells and the modulation of B- and T-cell subsets.

Methods

Participants and study design

Thirty-six HIV-1-infected adult patients (group I), enrolled by the Institute of Infectious and Tropical Diseases of University of Brescia (Italy) during the Simplified Sequencing THERapy trial (S.I.S.THER.), participated to this study. S.I.S.THER. was a 12 months long multicentre prospective randomized trial, in which HIV⁺ patients who had never been treated before, but requiring antiretroviral therapy according to the current guidelines for the use of antiretroviral therapy, were randomly assigned, in a one-to-one ratio, to receive either zidovudine + lamivudine + lopinavir/ritonavir or tenofovir + lamivudine + efavirenz [25]. Peripheral blood mononuclear cells (PBMCs), prepared by Ficoll-Hypaque density gradient centrifugation, were obtained from the blood of these patients before therapy initiation (T0),

after 6 (T6) and 12 (T12) months, and then stored and used for laboratory analysis. A further blood sample was obtained after 6 years of antiretroviral therapy (T72). The routine clinical examination, CD4⁺ T-cell count, and HIV-1 RNA quantification were assessed at all time points. A first control group (group II) consisted of 22 randomly selected HIV-1-infected patients who were regularly followed up in the HIV outpatient clinic, but did not need antiretroviral therapy according to the current guidelines. HIV-uninfected persons, matched by age and gender with the patients of group I in a two-to-one ratio, were selected as a second control group (group III). Only one blood sample was obtained from individuals of group II and III. The baseline characteristics of patients of group I and II and the immunovirological features observed during the follow-up in group I are summarized in Table 1.

The study was conducted in accordance with good clinical practice (ICH-E6). The trial and amendments received approval by the institutional review board/independent ethics committee (resolution of n° 33 of March 11, 2011) and the patients provided written informed consent before the S.I.S.THER. trial and for the present study as well.

Real-time PCR for KRECs, TRECs, IL-7 and IL-7R α quantification

DNA was extracted from about 3×10^6 PBMCs using the QIAamp DNA Blood Mini Kit (Qiagen, Valencia, CA), according to the manufacturer's instructions. KREC and TREC molecules were detected by a duplex quantitative real-time PCR, in which the simultaneous amplification of the two target sequences occurs in a single reaction, and the specific probes, labeled with different fluorescent dyes, allowed to separately quantify the amount of each target. The sequence of primers and probes for the signal joint regions of KRECs and TRECs, as well as for the reference gene, which was a fragment of the T-cell receptor alpha constant gene (TCRAC), have been previously described [23]. The PCR reactions were developed in 96-well optical reaction plates (Applied Biosystems, Foster City, CA) and the reaction mixture was prepared in a total volume of 25 μ L containing 12.5 μ L of 2x TaqMan Universal PCR master mix containing AmpErase UNG (Applied Biosystems), 900 nM forward and reverse primers, 200 nM probes, and 5 μ L of genomic DNA solution. Amplification of the TCRAC was done in the same plate. The conditions for the real-time PCR, performed on a 7500 Fast Real-Time PCR System (Applied Biosystems), were 50°C for 2 minutes and 95°C for 10 minutes, followed by 45 cycles of 95°C for 15 seconds and 60°C for 1 minute. All samples were measured in duplicate. The number of KREC, TREC and TCRAC molecules in the sample was extrapolated by

the standard curve obtained by serial dilutions (10^6 , 10^5 , 10^4 , 10^3 , 10^2 , and 10) of a linearized plasmid DNA, containing three inserts corresponding to fragments of KRECs, TRECs and TCRAC, which were amplified in each PCR plate. KREC and TREC copies were calculated per mL of blood by multiplying the number of KREC or TREC molecules in the sample by the lymphocyte plus monocyte count per mL of blood, as done by Chen et al. [26]. The quantity of TRECs per 10^6 PBMC was also reported, and their density per naive cells or per RTE cells was calculated dividing the value of TRECs/mL by the numbers of naive T cells/mL or RTE cells/mL.

One hundred and fifty ng of total RNA, extracted from PBMCs using NucleoSpin RNA II kit (Macherey-Nagel GmbH & Co. KG, Düren, Germany) were reverse transcribed into cDNA using random hexamers and Taqman reverse transcription reagents (Applied Biosystems). An equivalent of 22.5 ng of RNA was analyzed in each well on the 7500 Fast Real-Time PCR System using TaqMan Gene Expression Assay for IL-7 and IL-7R α , (IL-7: Hs00174202_m1 and IL-7R: Hs00902334_m1; Applied Biosystems) or primers and probe for glyceraldehyde 3-phosphate-dehydrogenase (GAPDH: forward primer: 5/GAAGGTGAAGGTCCGAGTC3/, reverse primer: 5/GAAGATGGTGATGGGATTTTC3/ and probe: Fam-CAAGCTTCCCGTTCTCAGCC-Tamra) synthesized according to the Applied Biosystems recommendations. Results, obtained using the comparative Cycle threshold (Ct) method with GAPDH as the reference gene and the RNA extracted from the pooled PBMCs of 10 healthy donors as the calibrator sample, were reported as the value of “- $\Delta\Delta$ Ct”, being $\Delta\Delta$ Ct = [(Ct target - Ct reference gene)_{patient} - (Ct target - Ct reference gene)_{calibrator}].

Cytofluorimetric characterization of lymphocyte subpopulations and IL-7R α analysis

B- and T-cell subsets were determined by six-colour flow cytometry analysis on the fresh whole blood obtained at T72 from group I patients and from both group II and III control individuals. Briefly, for the identification of B-cell subsets, 100 μ L of whole blood was stained with various combinations of optimal staining concentrations (previously determined by titrations) of peridin-chlorophyll protein-Cy5.5 anti-CD19, phycoerythrin-Cy7 anti-CD10, fluorescein isothiocyanate anti-IgD, and phycoerythrin anti-CD27 (BD Pharmingen, Heidelberg, Germany) monoclonal antibodies (mAbs). For T-cell subpopulation characterization the following mAbs were used: allophycocyanin-H7 anti-CD4, fluorescein isothiocyanate anti-CD45RA (BD Pharmingen), peridin-chlorophyll protein-Cy5.5 anti-CCR7 (BioLegend, San Diego, CA), and allophycocyanin anti-CD31 (Miltenyi Biotec, Bergisch Gladbach, Germany) mAbs. The staining was performed for 15 minutes at room temperature in the dark. Then, red blood cells were lysed with BD Pharm Lyse™ lysing solution (BD Pharmingen). Data were collected immediately using a 6-colour 2-laser BD FACSCanto II cytometer and analyzed with the FACSDiva software (BD Biosciences, San Jose, CA). B- and T-cell subsets were identified (as previously reported [27-30] and shown in the Additional file 1: Figure S1) as: CD19⁺CD10⁺ immature, CD19⁺CD10⁻IgD⁺CD27⁻ naive mature, CD19⁺CD10⁻IgD⁻CD27⁺ memory switched and CD19⁺CD10⁻IgD⁺CD27⁺ memory unswitched B cells; CD4⁺CD45RA⁺CCR7⁺ naive, CD4⁺CD45RA⁺CCR7⁻CD31⁺ RTE, CD4⁺CD45RA⁻CCR7⁺ central memory (T_{CM}) and CD4⁺CD45RA⁻CCR7⁻ effector memory (T_{EM}) T cells. The level of cell surface expression

of IL-7R α was studied by analyzing the median fluorescence intensity (MFI) of PBMCs incubated with anti-CD4 and phycoerythrin-Cy7 anti-CD127 (eBioscience, San Diego, CA) mAbs.

Statistical analysis

Univariate comparisons between log KREC, log TREC, IL-7, and IL-7R α means, calculated in group I, II and III (and reported in the manuscript along with their standard deviation), were performed by ANOVA followed by the Student-Newman-Keuls test for all the pairwise comparisons, whereas changes of their mean values over the follow-up were assessed by repeated measure ANOVA, followed by Bonferroni-corrected multiple tests. A mixed-model ANOVA for repeated measures was used to compare the between-group differences in TRECs, KRECs or CD4 during the follow-up time, and planned orthogonal contrasts (with Bonferroni-corrected p-values) were performed to compare the group means at the time points of interest. Spearman's rank correlation coefficients were used to assess the correlations of the immunological parameters with age. To evaluate the impact of the immunological and virological parameters on therapy-induced KREC or TREC changes in patients of group I, two multivariable linear regression models were fitted, after performing univariable linear regressions aimed at identifying significant factors and at excluding confounding ones. The differences between the log-value of KRECs/mL and TRECs/mL found at T72 and T0 were chosen as the dependent variables. As independent variables were tested the basal levels of several immune parameters that could have affected the immune recovery, as listed in Table 2. As a result, the following covariates, whose p-value resulted at least <0.10, were chosen as predictors in the final multivariable models: the pre-therapy level of log KRECs/mL or log TRECs/mL (which were included in order to adjust for their potential confounding value), the infection duration (estimated from the presumed time of infection,

which corresponds to the date of the first positive HIV-1 test), the pre-therapy viremia, and the pre-therapy CD4⁺/CD8⁺ cell ratio. The CD4⁺ cell count was excluded because it was highly correlated to the CD4⁺/CD8⁺ cell ratio. Accordingly, the obtained multivariable regression coefficients represented the variation of log KREC or log TREC differences from T72 to T0, per unit change of the listed independent variables (Table 3); their values are reported in the manuscript, after anti-log transformation, as the percent change of log KREC or log TREC T72-to-T0 variations. The Kruskal-Wallis test, followed by the Dunn's post-hoc test, was employed to compare flow cytometry results, which are reported herein as medians and depicted as box-and-whisker plots. Unless otherwise specified, the criterion for statistical significance was set at $p < 0.05$.

Results

Quantification of KRECs and TRECs

The number of KRECs and TRECs of HIV-1-infected patients (group I: subjects treated with cART and followed up for 72 months; group II: HIV-1-infected patients naive for therapy) was compared to that of matched HIV-1 uninfected controls (group III). KRECs of patients of group I at T0 (4.15 ± 0.37 log KRECs/mL) were similar to those of group III (4.13 ± 0.27 log KRECs/mL) and significantly higher than those of group II (3.94 ± 0.35 log KRECs/mL, $p < 0.05$; Figure 1A). In addition, the number of KRECs found at T0 was not modified by 6 or 12 months of therapy (T6: 4.09 ± 0.42 , T12: 4.07 ± 0.39 log KRECs/mL, $p = \text{NS}$), while the long-lasting treatment resulted in a significant decrease in new B-cell release from the bone marrow (T72: 3.84 ± 0.49 log KRECs/mL, $p < 0.01$), so that KREC⁺ cells of group I at T72 became significantly lower than those of group III ($p < 0.05$), but remained similar to those of group II ($p = \text{NS}$). The number of KRECs was not correlated with increasing age in any of the groups (data not shown), while only in group I it was positively correlated

with the number of CD4⁺ cells before starting cART (T0; $r = 0.38$; $p < 0.05$) and after 6 months of therapy (T6; $r = 0.51$; $p < 0.01$), but not after one year of treatment (T12) or at the end of the follow-up (T72).

The number of TREC⁺ cells, before starting cART, was significantly lower in group I than in both control group II and III (2.67 ± 0.87 log TRECs/mL vs. 3.53 ± 0.37 log TRECs/mL, $p < 0.05$ and vs. 3.71 ± 0.55 log TRECs/mL, $p < 0.05$; Figure 1B), and no correlation between TRECs and patient age was observed in this group (data not shown). In contrast, and also differently from KRECs, TRECs decreased with older age both in group II ($r = -0.62$; $p < 0.001$) and in group III ($r = -0.46$; $p < 0.001$), with an average TREC⁺ cell loss of 55% every 10 years. Moreover, the number of TREC-containing

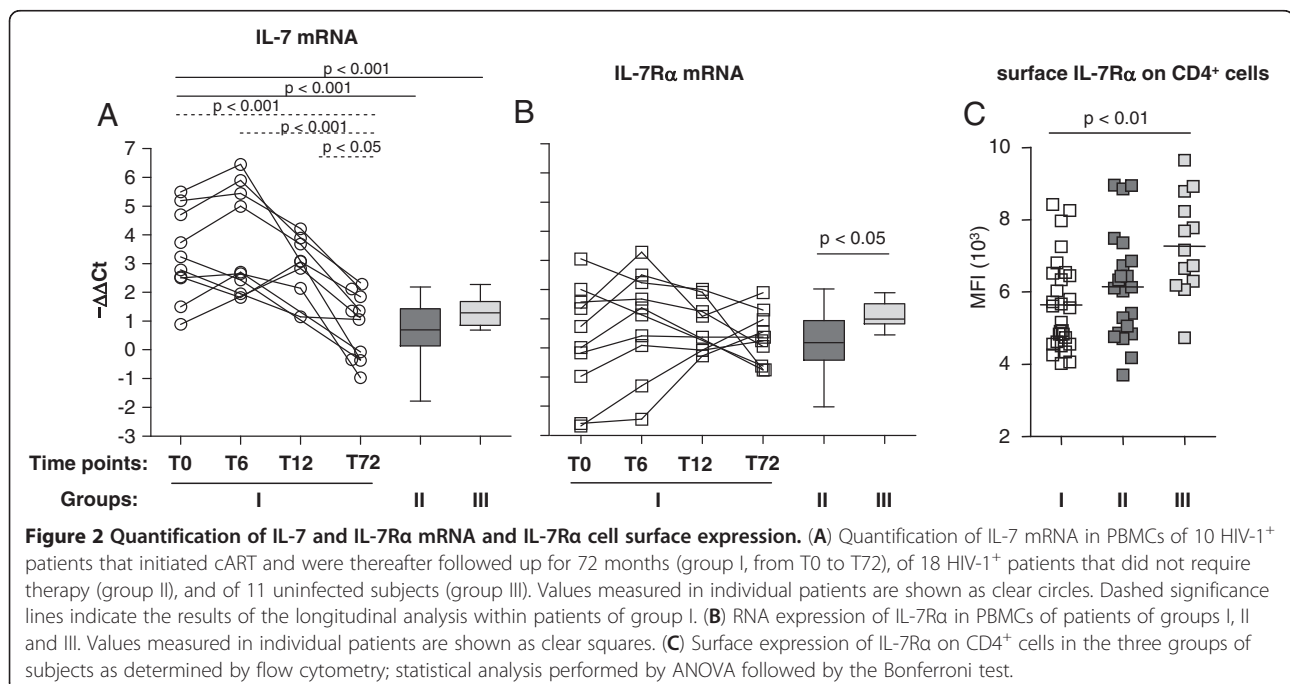

cells of group I, but not of group II, was positively correlated to the number of CD4⁺ cells at T0 ($r=0.57$, $p<0.01$), T6 ($r=0.40$; $p<0.01$) and T12 ($r=0.41$; $p<0.01$), but not at T72. An increase of TREC⁺ cell production in group I was already evident at 6 months of therapy (T0: 2.67 ± 0.87 log TRECs/mL vs. T6: 3.09 ± 0.59 log TRECs/mL, $p<0.001$) and persisted also after the long-lasting treatment (T72: 3.22 ± 0.44 log TRECs/mL, $p<0.01$), but it never reached the levels observed in control group II or III (3.53 ± 0.37 log TRECs/mL and 3.71 ± 0.55 log TRECs/mL, respectively; $p<0.05$). A similar pattern of TREC modulation was observed if TRECs were calculated per 10^6 PBMC (see Additional file 1: Figure S2A); furthermore, the fold change increases from T0 to T6, T12 and T72 were comparable when TRECs were expressed in either forms (see Additional file 1: Figure S2B). Because patients of group I had a heterogeneous number of CD4⁺ cells that, at T0, was correlated to KREC and TREC levels, they were stratified into two groups: patients with a CD4⁺ cell count lower (21 out 36) or higher (15 out 36) than 200 cells/ μ L. While KRECs did not show a different trend in the two groups at any time point (Figure 1C), the level of TREC was differentially modulated, with a pattern not reflecting that of CD4⁺ cell increase. Indeed, at T0, TRECs of patients with CD4⁺ cells $<200/\mu$ L were the lower (2.21 log TRECs/mL vs. 2.99 log TRECs/mL, $p<0.001$), but at T72 they increased up to the level found in patients with CD4⁺ cells $>200/\mu$ L (3.20 log TRECs/mL vs. 3.22 log TRECs/mL, $p=NS$), whose TRECs, on the other hand, had remained substantially

unchanged (Figure 1D). In contrast, the total CD4⁺ cell count grew very similarly in the two groups, thus remaining significantly different at all time points ($p<0.001$; Figure 1D).

Measure of IL-7 and IL-7R α

To evaluate whether IL-7 and IL-7R α could be involved in the modulation of KRECs and TRECs of cART treated patients, we quantified the RNA of the two targets by real-time PCR in 10 patients of group I. These cART-treated patients showed a wide range of IL-7 RNA values: the mean level of IL-7 RNA relative expression, which, before therapy, was significantly higher than that of subjects of group II and III (T0: 3.26 ± 1.53 vs. group II: 0.69 ± 0.96 , $p<0.001$; and vs. group III: 1.32 ± 0.52 , $p<0.001$), further increased after six months, but then decreased to reach the levels observed in both groups II and III after 6 years of therapy (T72: 0.81 ± 1.17 , $p<0.001$; Figure 2A). The levels of RNA for IL-7R α in group I were also highly heterogeneous at the first two time points of the follow-up, then the range of values tended to narrow at the following time points, but their mean value did not significantly change over time, nor there were any significant differences in comparison to that of patients of group II and controls of group III at any time point. However, the mean IL-7R α RNA level was lower in patients of group II than in group III (0.16 ± 1.03 ; 1.16 ± 0.47 , $p<0.05$; Figure 2B). Furthermore, the level of IL-7R α cell surface expression, calculated as the MFI of anti-CD127 mAb on CD4⁺ T cells, was lower in the patients treated for 6 years with cART

than in patients of group II and subjects of group III (5630 ± 1250 vs. 6157 ± 1498 vs. 7300 ± 1375 MFI; Figure 2C), even though the difference was significant only in comparison to group III ($p < 0.01$). These data are in agreement with those indicating that HIV-1 infection is associated with decreased IL-7R α expression on circulating T cells, and effective antiretroviral therapy only partially restores this defect [31,32].

Identification of factors influencing KREC and TREC production

To better assess how the immunological or virological parameters affected the observed therapy-induced KREC or TREC changes, we employed the linear regression analysis. First, a series of univariable regressions were fitted in order to identify significant covariates and putative confounding variables. Results showed that a lower increase of log TRECs/mL from T0 to T72 is to be expected in the presence of a higher basal log TRECs/mL or of a higher CD4⁺/CD8⁺ ratio at T0, and that greater log KRECs reductions could be ascribed to longer infection duration before therapy initiation. Of note, neither the different therapy arm nor the presence of HCV co-infection affected KREC and TREC changes (Table 2).

The effects of these variables were then reciprocally adjusted by fitting multivariable regressions (Table 3), which, after anti-log conversion of the obtained coefficients, indicated that the TREC increase over time was 72% lower for each additional 1-log of basal TREC value and 38% lower for each 10-fold increase of blood HIV-1-RNA. At the same time, a higher basal level of log KRECs/mL accounted for a stronger reduction in the release of new B cells from the bone marrow following the cART, in the amount of a 66% decrease for each additional 1-log of basal KRECs/mL, whereas higher basal CD4⁺/CD8⁺ ratios determined a tapering of KREC decrease in the measure of 22% for each 0.10-higher CD4⁺/CD8⁺ ratio. Furthermore, for any additional year of infection duration at the moment of therapy start, the decrease of KRECs from T0 to T72 was enhanced by 23%, whereas the increase of TRECs was reduced by a further 14%.

Cytofluorimetric analysis of B- and T-cell subsets

The percentage (Figure 3A) and number (Figure 3B) of B- and T-cell subsets were determined by cytofluorimetric analysis on fresh blood samples of the HIV-1-infected patients of group I obtained after 72 months of therapy, which were compared to those of subjects of group II and group III. Patients of group I had a lower percentage of immature B cells with respect to those of group II (6.0% vs. 12.1%, $p < 0.05$), a percentage and number of naive and memory switched B cells similar to

those of the other two groups ($p = \text{NS}$) and a lower percentage of memory unswitched B cells in comparison to that of individuals of group II and III (12.54% vs. 16.2% vs. 22.0%, respectively, $p < 0.05$). Within the T-cell compartment, the percentage, but not the number, of naive cells and of RTE, which are the cells that were recently released from the thymus, was lower in group I than in group II (23.4% vs. 33.4%; $p < 0.05$), but similar to that of group III (29.0%; $p = \text{NS}$). Since changes in proliferation or loss rate occurring within naive and RTE cells may interfere with the measure of thymic export, the number of TRECs within naive and RTE populations of untreated patients of group I and II was evaluated. As shown in the Additional file 1: Figure S3A, TRECs were not different ($p = \text{NS}$) in the two T-cell subsets. Furthermore, the slope and intercept of the regression lines, obtained by fitting a model with TRECs/mL as dependent variable and naive/mL or RTE/mL as independent variables, were similar (see Additional file 1: Figure S3B). Therefore, it is likely that no significant variations occurred in the number of naive and RTE cells that would induce a misinterpretation of TREC data.

Patients of group I showed a significantly higher percentage and number of T_{CM} lymphocytes in comparison to those of group II subjects (43.5% vs. 27.1%, $p < 0.05$; and 265 cells/ μL vs. 175 cells/ μL , $p < 0.05$; Figure 3A, B), who, in turn, had a significantly lower percentage and number of these cells in respect to the healthy individuals of group III (27.1% vs. 40.5%, $p < 0.05$; and 175 cells/ μL vs. 255 cells/ μL , $p < 0.05$). No significant differences were observed for T_{EM} cells in the three groups.

Discussion

The extent of thymic output is one of the most important markers of the T-cell immune recovery in HIV infection, but this information remains incomplete if not complemented with the assessment of B-cell compartment that is known to be also impaired during HIV infection. Indeed, in HIV-1-infected individuals, the loss of memory B cells, together with an altered differentiation of naive B cells, results in the production of a low quantity of antigen specific antibodies [33]. However, given the various B-cell sources, routine serotyping does not allow discrimination between antibodies produced by newly developed B cells and those produced by old mature B cells that have been expanded in the periphery. If the antibody production is solely based on expanding mature B cells, antibody production will end as the old B cells die off. Therefore, the integrity and efficacy of regeneration of the B-cell compartment in HIV⁺ patients should also be monitored by distinguishing newly produced B cells from the old ones. We had previously validated a method based on the quantification of KRECs and TRECs which appears to provide a reliable

Figure 3 Quantification of B- and T-cell subpopulations. (A) Percentage (gray boxes) and (B) number (clear boxes) of immature, naive, memory switched, and memory unswitched B cells, as well as of naive, recent T emigrants (RTE), central memory (T_{CM}) and effector memory (T_{EM}) T cells in patients treated for 72 months with cART (group I), patients not requiring therapy (group II), and non-infected individuals (group III). Horizontal lines indicate the significant differences (all p < 0.05).

quantification of both newly produced B and T cells [23,24]. Thus, we applied the KREC/TREC assay to monitor the immunoreconstitution of HIV-1⁺ patients. Following what suggested by Ribeiro and Perelson [34] and Lorenzi et al. [35], we expressed the results of our analysis in terms of KRECs/TRECs per mL of blood in order to overcome the bias related to the extensive peripheral cell divisions that would dilute TREC content and make any KREC/TREC values calculated “per 10⁶ unsorted PBMCs” difficult to interpret, in particular in

subjects with a chronic immune activation and increased peripheral lymphocyte proliferations, such as HIV-infected patients.

While patients of group I at T0 and of group II were all not undergoing cART, different levels of KRECs and TRECs were found in the two groups. However, these patients represent two different types of naive subjects because those of group II still maintained a quite conserved immune system (CD4⁺ cell count >350/μL) and did not need antiretroviral therapy

according to the current guidelines for the diagnosis and treatment of HIV-1 infection, whereas those of group I at T0 were patients with a number of CD4⁺ T cells <350/μL or with clinical AIDS-defining conditions at diagnosis. They were diagnosed with HIV-1 infection when the disease had already progressed to a severe level of immune deterioration, so that after starting antiretroviral therapy and despite full viral suppression, some of them showed a suboptimal immune recovery.

We also found that the kinetics and the timings of B- and T-cell release from the bone marrow and thymus during cART are completely different. KREC production, that remains unchanged until one year of therapy, decreases following prolonged therapy to levels that were similar to those of therapy-free HIV-1⁺ patients, but lower than those of uninfected subjects. This result is not unexpected since it has been previously demonstrated that, in patients with idiopathic CD4⁺ lymphocytopenia, the percentage of immature/transitional B cells, that are known to contain the highest number of KRECs [36], is inversely correlated with the CD4⁺ T-cell count [37]. Accordingly, in our patients, the lowest levels of KRECs were observed in the long-lasting treated patients who also showed the higher CD4⁺ lymphocyte count. Furthermore, in patients with idiopathic CD4⁺ lymphocytopenia, the expansion of immature/transitional B cells appears to be associated with elevated serum levels of IL-7 [37]. Previous studies have shown a significant increase of IL-7 level also in lymphopenic states due to HIV-1 infection and currently there are ongoing clinical investigations on IL-7 as a potential anti-HIV therapy [38,39]. In HIV-infected patients, the administration of IL-7 increases in the proportion of immature/transitional B cells [39]. Thus, the low release of B cells from the bone marrow we have observed in our patients after prolonged cART may be related to the levels of IL-7 that, although being very high in the patients that initiated cART, progressively decreased to levels comparable to those observed in patients not requiring therapy and healthy controls. Therefore, since we also found that prolonged cART induces an increase of thymic output, the concomitant administration of cART and IL-7 may represent a novel strategy for improving the immune reconstitution in chronic HIV infection. In this regard, KREC and TREC quantification could be a useful tool for monitoring the efficacy and safety of IL-7-based therapies [40]. In addition, the observed decrease of memory unswitched B cells (feature that completes data by Chong et al. [41], reporting a decline in total memory B cells), together with the decline in new B-cell production, is likely to contribute to the reduced humoral immune response observed in HIV-1⁺ patients despite antiretroviral treatment.

As already reported by several authors [42,43], we found that TREC production was increased following cART initiation, reached a plateau after 12 months, and remained stable during several years of therapy, although never reaching the levels observed in the HIV-1-infected patients not requiring therapy or in the uninfected controls. We also observed the known dependency of TRECs on ageing [35] only in HIV-uninfected controls and in the HIV-1-infected patients that did not need therapy, but not in those who underwent cART. This is likely to be due to an incomplete immune reconstitution as indicated by the persistent low number of CD4⁺ cells found in several patients of this group. Furthermore, the increase in TRECs appears to be more evident in patients with a lower viral load, a lower CD4⁺/CD8⁺ ratio, or lower CD4⁺ cell counts before therapy beginning. In particular, before cART, TRECs were significantly lower in those patients with CD4⁺ cells <200/μL than in those with CD4⁺ cells >200/μL, although they increased only in the patients with low CD4⁺ cells, so that the difference was abolished after prolonged therapy. The two anti-viral drug combinations appear not to affect the extent of new B- and T-cell mobilization that, on the contrary, was affected by the duration of the infection before therapy initiation. Indeed, each year of infection before therapy weakens the recovery of TRECs and favors the decrease of KRECs observed in most patients after treatment. While it has been previously reported that the early initiation of an antiretroviral therapy restores the memory B-cell number, though only temporarily [44,45], to our knowledge this is the first report linking the extent of B- and T-cell release from the production site following long-lasting antiretroviral therapy to the duration of HIV-1 infection before treatment initiation.

Flow cytometry results partially overlap those obtained by real-time PCR, because they confirm the lower levels of immature B cells, which are, for the most part, recently produced B cells, and of naive and RTE T lymphocytes in long-lasting treated patients in respect to patients that did not need therapy (but only if calculated as percentage and not as total number). Furthermore, the increase of T_{CM} cells already observed by Hodge et al. [46] after 2 years of antiretroviral therapy, seems to persist also after long-lasting treatment.

Conclusions

In conclusion, the analysis of KRECs and TRECs appears to be a valuable aid for the fine immunological characterization of HIV-1⁺ patients treated with cART. Furthermore, because the administration of recombinant IL-7 in humans increases the number of TREC-containing cells [47] and high IL-7 serum levels appear to be associated with the expansion of immature/transitional

B cells, our combined TREC and KREC assay could be useful for the monitoring of IL-7 based therapies.
