Abstract

Tannerella forsythensis (*Bacteroides forsythus*), an anaerobic Gram-negative species of bacteria that plays a role in the progression of periodontal disease, has a unique bacterial protein profile. It is characterized by two unique protein bands with molecular weights of more than 200 kDa. It also is known to have a typical surface layer (S-layer) consisting of regularly arrayed subunits outside the outer membrane. We examined the relationship between high molecular weight proteins and the S-layer using electron microscopic immunolabeling with chemical fixation and an antigen retrieval procedure consisting of heating in a microwave oven or autoclave with citraconic anhydride. Immunogold particles were localized clearly at the outermost cell surface. We also used energy-filtering transmission electron microscopy (EFTEM) to visualize 3, 3'-diaminobenzidine tetrahydrochloride (DAB) reaction products after microwave antigen retrieval with 1% citraconic anhydride. The three-window method for electron spectroscopic images (ESI) of nitrogen by the EFTEM reflected the presence of moieties demonstrated by the DAB reaction with horseradish peroxidase (HRP)-conjugated secondary antibodies instead of immunogold particles. The mapping patterns of net nitrogen were restricted to the outermost cell surface.

Key words: antigen retrieval, immunolabeling, *Tannerella forsythensis*

For electron microscopic immunocytochemistry, general ultrastructure sometimes has been sacrificed to obtain specific, efficient and dense labeling. Antigenicity often is lost by the conventional postfixation of tissue with OsO₄ (Roth et al. 1981). Omission of OsO₄, however, results in poor membrane contrast and thereby compromises visualization of

fine structure. Therefore, several investigators have used potassium ferrocyanide-reduced OsO₄ to achieve excellent preservation of ultrastructure and good immunoreactivity of the antigens (Tamaki and Yamashina 1994, Tamatani et al. 1995). Postfixation by potassium ferrocyanide-reduced OsO₄ has been applied widely to obtain fine membrane structures with clear contrast for morphological observation by transmission electron microscopy (Doine et al. 1984, Rambourg et al. 1993).

Antigen retrieval can recover antigens masked by fixation, storage, processing and resin interactions. Such procedures have been used extensively for

light and electron microscopy (Xiao et al. 1996, Shi et al. 2001, Calabria et al. 2004, Martins et al. 2011). Antigen retrieval involves heating in buffers at different pH and in the presence of enzymes (Cattoretto et al. 1993, von Wasielewski et al. 1994, Shi et al. 1995, Taylor et al. 1996, Pileri et al. 1997, Mighell et al. 1998). A common antigen retrieval treatment includes the use of citrate buffer, Tris-HCl containing 5% urea, and EDTA solutions combined with heating in a microwave oven or autoclave (Nami-matsu et al. 2005). Citraconylation by citraconic anhydride was introduced as a method for reversible blocking of protein amino groups (Dixon and Perham 1968). Using this principle, Namimatsu et al. (2005) reported that by incorporating citraconic anhydride and heat, successful antigen retrieval in formalin fixed tissues is feasible. Because glutaraldehyde basically is similar to formaldehyde in its mechanism of action, these investigators explored whether the same method could work on glutaraldehyde fixed tissues for use in immunoelectron microscopy.

We observed earlier that 230 and 270 kDa proteins might be a component of the S-layer of bacteria based on the results of our immunoelectron microscopic study of 4% paraformaldehyde-0.05% glutaraldehyde fixation without OsO₄ or after freeze-substitution (Higuchi et al. 2000, Moriguchi et al. 2003). Sabet et al. (2003), however, reported that the S-layer consists of 200 and 210-kDa proteins. In their study, the bacterial cells were re-suspended in 0.1 M cacodylate buffer with 1% glutaraldehyde and postfixed with 1% OsO₄.

A large number of antigen particles and their clear localization are important requirements for optimal presentation of tissue antigen for immunohistochemistry. Therefore, we tried an antigen retrieval method that combined citraconic anhydride and microwave oven or autoclave heating for post-embedding immunoelectron microscopy; this resulted in better retention of specific binding of gold-labeled particles and rich nitrogen, which reflects the presence of 3, 3'-diaminobenzidine, tetrahydrochloride (DAB) moieties detected by energy-filtering transmission electron microscopy (EFTEM). That is, peroxidase-DAB reaction leads to DAB polymerization via nitrogen atoms (Vannier-Santos and Lins 2001). Two different modes of the EFTEM (Golecki and Heinrich 1991, Kortje et al. 1991, Fehrenbach et al. 1992, Huxham et al. 1992, Busch et al. 1993, Beckers et al. 1994) have been used for electron spectroscopic images (ESI) and electron energy-loss spectroscopy (EELS). Parallel-EELS is an additional tool. This procedure was performed

using the commercially-available LEO LIBRA 120 Omega EFTEM.

Materials and methods

Cell culture

T. forsythensis ATCC 43037 was obtained from A. Tanner (Forsyth Institute, Boston, MA). This strain was grown anaerobically for 7 days on Brucella agar (Difco Laboratories, Detroit, MI) supplemented with 5% laked-rabbit blood, 2.5 µg/ml hemin, 5.0 µg/ml menadione, 0.01% dithiothreitol, and 10 µg/ml *N*-acetylmuramic acid at 37° C. The bacteria were harvested by scraping colonies from Brucella agar plates. The cells were washed once with 10 mM Tris-HCl, pH 7.4, containing 0.15 M NaCl. The washed cells were disrupted by sonication at 5° C for 15 min with a Bioruptor UCD-200T (Cosmo Bio Co., Ltd., Tokyo, Japan) in the presence of proteinase inhibitors (0.25 mM *N*- α -*p*-tosyl-L-lysine chloromethyl ketone, 0.2 mM phenylmethylsulfonyl fluoride and 0.1 mM leupeptin).

Antigen preparation

Whole cell extracts were obtained as a supernatant after unbroken cells were removed by centrifugation at 1,000 × g for 10 min. Envelope and soluble fractions were separated by ultracentrifugation of the whole cell extracts at 143,000 × g for 60 min as described previously (Higuchi et al. 2000). The envelope fraction was subjected to sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) (Lugtenberg et al. 1975). The 270 kDa major protein was used as an antigen for preparing a specific antiserum. To do this, the 270 kDa band was cut from the SDS-PAGE preparative gel and purified. Antiserum against the 270 kDa protein was raised in a rabbit. The specificity of the antiserum was verified by Western blot analysis as described previously (Higuchi et al. 2000).

Cell preparation

T. forsythensis cells were fixed first with 4% paraformaldehyde-0.05% glutaraldehyde in phosphate-buffered saline, pH 7.4, (PBS) at 4° C for 60 min, then postfixed with 1% potassium ferricyanide-reduced OsO₄ at 4° C for 60 min. These samples were dehydrated and embedded in LR White (London Resin Co., Ltd., Berkshire, England). The resin was polymerized at 55° C for 24 h.

Antigen retrieval

Nickel grids (Veco, 200-mesh) with ultrathin sections of LR White embedded blocks were immersed in 1% citraconic anhydride solution (Nissin EM Co., Ltd., Tokyo, Japan), placed in a microwave oven (MI-77 Azumaya, Co., Tokyo, Japan) and heated on and off automatically to keep the temperature at 100° C for 15 min (net microwave irradiation of 11.7 min) or placed in an autoclave (MAC-280, ELK Corp., Tokyo, Japan) at 115° C for 30 min or 135° C for 15 min. After this, the grids in the citraconic anhydride solution were allowed to cool to room temperature for 30 min.

Immunogold labeling

After antigen retrieval, nonspecific staining was blocked by treatment for 30 min with 1% bovine serum albumin (BSA) in PBS. Immunogold reactions were carried out using an indirect method. The grids were treated for 12 h by inserting them in drops of antiserum diluted 500-fold in 1% BSA-PBS. After two washes with PBS, the grids were incubated for 1 h in goat anti-rabbit IgG labeled with 20 nm gold, secondary antibodies (EY Laboratories, Inc., San Mateo, CA) diluted 50 fold in 1% BSA-PBS, and washed twice with PBS. The immunolabeled sections were counterstained with uranyl acetate and lead citrate. They then were examined under an electron microscope JEM 1210 (JEOL, Tokyo, Japan).

ESI and parallel-EELS

After antigen retrieval, the grids treated in drops of antiserum were incubated for 12 h in HRP-conjugated secondary antibodies instead of immunogold particles. The immuno-HRP labeled sections then were incubated for 1 h in DAB reaction solution consisting of 0.1% DAB and 0.001% H₂O₂. To gain ESI and parallel-EELS of the nitrogen, which is reflected by the presence of DAB moieties, we used the EFTEM, Carl Zeiss LIBRA 120 (Carl Zeiss, Oberkochen, Germany) operated at 120 kV. To analyze ESI, a slow scan CCD camera linked to a computer recorded energy-filtered images of identical elements. The transmission image, a zero-loss image using only a non-scattered electron beam, was recorded. The ESI of the nitrogen was obtained from the ΔE_{\max} at the 410 eV edge of K edge. To identify quantitatively the edge, we removed the background using a three-window method. The corresponding pixel signals were recorded for the first window, ΔE_{w1} , at 382 eV and the second window, ΔE_{w2} , at 350 eV below the edge.

Additional tool parallel-EELS is a technique for rapid analysis of radiation sensitive specimens.

Results

Immunogold labeling

In control sections without antigen retrieval, the cell wall consisted of a cytoplasmic membrane and an outer membrane with two electron-dense layers, as well as an S-layer in which the cells were enclosed. The S-layer showed serrated structural subunits. Moreover, immunogold particles were localized at the outermost cell surface where the S-layer was present (Fig. 1).

Immunogold particles that had been autoclaved (115° C or 132° C) or microwaved (100° C with citraconic anhydride) were observed by electron microscopy. Our ultrastructural observation of both retrieval methods revealed moderately decreased cytoplasm (Figs. 2a, b, d and 3a, c) compared to the control (Fig. 1). There was no damage to the ultrastructural integrity of the cytoplasmic membrane or outer membrane. Each membrane consisted of two electron-dense layers (Figs. 2c, e and 3b, d). In all heating retrievals with citraconic anhydride, the reactivity of immunogold particles was better than that of the controls, which permitted clear observation of antigen retrieval effects. (Figs. 2 and 3).

ESI and parallel-EELS

The ESI and parallel-EELS analysis showed the distribution of the nitrogen in the cytoplasm of *T. forsythensis* without microwave antigen retrieval at 100° C. The EFTEM produced a zero-loss transmission image (Fig. 4a). The distribution of net nitrogen was demonstrated (Fig. 4b) using the three-window method at ΔE_{w1} (Fig. 4e), ΔE_{w2} (Fig. 4d) and ΔE_{\max} 410eV of K edge of nitrogen (Fig. 4f).

Fig. 1. Immunogold labeled *T. forsythensis* cells. Control section without antigen retrieval treatment. Cytoplasmic membrane (CM) and outer membrane (OM) consisted of two electron-dense layers. Serrated subunits of S-layer (S) are shown.

Fig. 2. Low (b, d) and high (a, c, e) magnification micrographs of immunogold-labeled *T. forsythensis* cells after antigen retrieval by heating with the autoclave. a) Autoclaved at 115° C with 1% citraconic anhydride. b and c) Autoclaved at 132° C with distilled water. d and e) Autoclaved at 132° C with 1% citraconic anhydride. Moderately decreased cytoplasm (a, b, d) compared to control cytoplasm (Fig. 1) without damage to the ultrastructural integrity of the cytoplasmic membrane and outer membrane (c, e). Immunogold-particles in a, c, e showed greater reactivity than the control (Fig. 1). CM, cytoplasmic membrane; OM, outer membrane; S, S-layer.

Figure 4c shows parallel-EELS analysis of the circle in Fig. 4b. A small amount of endogenous nitrogen was found in the cytoplasm. On the other hand, the same ESI and parallel-EELS analysis showed the distribution of nitrogen in the cytoplasm of *T. forsythensis* after microwave antigen retrieval at 100° C using 1% citraconic anhydride with or without the DAB reaction solution (consisting of 0.1% DAB and 0.001% H₂O₂). The microwave antigen retrieval treatment caused the nitrogen signals to disappear completely (data not shown) compared to Fig 4, which shows endogenous nitrogen distribution.

Finally, ESI analysis demonstrated the distribution of nitrogen (the DAB reaction solution consisting

of 0.1% DAB, 0.001% H₂O₂ and HRP-conjugated secondary antibodies instead of immunogold particles) onto a structural image of the cytoplasm of *T. forsythensis* (after microwave antigen retrieval at 100° C with 1% citraconic anhydride). The EFTEM produced a zero-loss transmission image (Fig. 5a). The distribution of net nitrogen was demonstrated (Fig. 5b) by using the three-window method at ΔE_{w1} (Fig. 5e), ΔE_{w2} (Fig. 5d) and ΔE_{max} 410ev of K edge (Fig. 5f). Nitrogen distribution (Fig. 5b) in red was superimposed on the zero-loss transmission image (Fig. 5a) and strictly corresponded with the outermost cell surface where the S-layer was present (Fig. 5g). Figure 5c shows parallel-EELS analysis of the circled area of Fig. 5b.

Fig. 3. Low (a, c) and high (b, d) magnification micrographs of immunogold-labeled *T. forsythensis* cells after antigen retrieval by heating with the microwave oven. Microwaved at 100° C with 1% citraconic anhydride. Moderately decreased cytoplasm (a, c) compared to control cytoplasm (Fig. 1) without damage to the ultrastructural integrity of cytoplasmic membrane and outer membrane (b, d). Immunogold-particles in (b) and (d) showed greater reactivity than the control (Fig. 1). CM, cytoplasmic membrane; OM, outer membrane; S, S-layer.

Discussion

The human oral cavity harbors more than 500 species of bacteria. Periodontitis, a bacterial inflammatory disease that leads to tooth loss, is believed to result from infection by a select group of Gram-negative periodontal pathogens including *Porphyromonas gingivalis*, *Treponema denticola*, and *Tannerella forsythensis*. *T. forsythensis* is characterized by two unique protein bands with molecular weights of more than 205 kDa as shown by SDS-PAGE (Tanner et al. 1986). The upper protein band is the 270 kDa protein. Ultrastructurally, many bacteria and archaea have a typical S-layer consisting of serrated subunits outside the outer membrane (Tanner et al. 1986, Kerosuo 1988, Sleytr and Beveridge 1999, Sara and Sleytr 2000). We confirmed by electron microscopy that the S-layer was located outside the outer membrane. The objective of our earlier study was to investigate any relationship between the S-layer and the 270 kDa protein in *T. forsythensis* (Higuchi et al. 2000). The cells were fixed with 4% paraformaldehyde-0.05% glutaraldehyde containing 4% sucrose and 0.05% calcium chloride, and postfixed with 0.5% uranyl acetate. We found that immunogold particles were localized at the outermost cell surface when antiserum was used, but not when pre-immune serum was used (Higuchi et al. 2000). In the work reported here, we applied antigen retrieval using citraconic anhydride solution and microwave or autoclave heating for post-embedding immunoelectron microscopy. Citraconic anhydride reacts

with the free amino groups of proteins and replaces the NH^+ groups of lysyl residues with negatively charged carboxyl groups (Dixon and Perham 1968, Habeeb and Atassi 1970).

Namimatsu et al. (2005) explored the use of citraconic anhydride as a reversible blocker of protein amino groups during formaldehyde and glutaraldehyde tissue fixation. Citraconic anhydride can chemically modify amino groups that are the main targets of these fixatives and the reaction can be reversed later for immunoreactions. Like formaldehyde, glutaraldehyde reacts mainly with lysyl residues; some reaction occurs also with tyrosyl, histidyl, and sulfhydryl residues. It is possible that this approach could make possible the preservation of both ultrastructure and immunoreactivity for formalin fixed tissues. Similarly, antigen retrieval permits successful pre-embedding immunoelectron microscopy of glutaraldehyde fixed tissues (Dai et al. 2004). Moreover, Leong et al. (2010), exploring a suggestion by Namimatsu et al. (2005) that citraconic anhydride might be a suitable antigen retrieval reagent, compared the immunostaining of 65 common diagnostic antigens following microwave antigen retrieval and confirmed that citraconic anhydride is a useful antigen retrieval compound, especially when used with microwave irradiation.

In addition to finding that immunogold particles were clearly localized at the outermost cell surface where the S-layer is located, we observed by electron microscopy that there was moderately decreased cytoplasm compared to controls after both heating

Fig. 4. ESI and parallel-EELS analysis showed the distribution of nitrogen in the cytoplasm of *T. forsythensis* without microwave treatment at 100° C; cells only. A small amount of endogenous nitrogen was observed in the cytoplasm. a) Zero-loss transmission image. b) Background removed net ΔE_{\max} 410 eV. c) Parallel-EELS analysis of the circled area of Fig. 4b. d) The second window of ΔE_{w2} 350 eV. e) The first window of ΔE_{w1} 382 eV of nitrogen. f) ΔE_{\max} 410 eV of K edge of nitrogen.

retrieval methods with citraconic anhydride. There was no damage to the ultrastructural integrity of the cytoplasmic membrane or outer membrane; each membrane consisted of two electron-dense layers. We concluded that antigen retrieval at high temperature in citraconic anhydride may damage the cytoplasmic ultrastructure.

The use of peroxidase and DAB for ultrastructural cytochemistry was introduced by Graham and Karnovsky (1966a,b) to trace endocytosis, but it also has been employed for demonstrating catalase (Moriguchi et al. 1984) and cytochrome oxidase (Hirai et al. 1989, Moriguchi et al. 1998), and for detecting endogenous peroxidase activity (Moriguchi et al. 2000). Oxidation causes DAB polymerization via nitrogen atoms and the resulting polymer is highly osmiophilic and insoluble, which allows easy identification of electron-dense precipitates of the enzymatic reaction product with minimal diffusion artifacts (Vannier-Santos and Lins 2001). Therefore, we used EFTEM to visualize also the enzyme reaction product (Moriguchi et al. 2008). The immunocytochemical localization of colloidal gold particle-conjugated secondary antibodies cor-

responded to the nitrogen identified by the maximal electron energy loss at 410 eV (K edge) in the ESI analysis. As reported earlier, ESI and EELS analyses under the EFTEM have been applied to demonstrate isolated ferritin particles (Beckers et al. 1994), calcium elements of plant root caps (Busch et al. 1993), iodine-containing anti-cancer drug meta-iodobenzyl guanidine (Huxham et al. 1992), phosphorus in mammalian lung parenchyma (Fehrenbach et al. 1992) and cyanobacteria (Golecki and Heinrich 1991), and calcium-ATPase in synaptic terminals (Kortje et al. 1991). These methods are fairly reliable and useful for analyzing several elements in biological materials; they are especially useful for mapping analysis compared to X-ray microanalysis. In addition, the three-window method easily removes the background. Moreover, the parallel-EELS is a method for analyzing radiosensitive samples quickly (Kortje 1994, Moriguchi et al. 2011) and this enabled us to confirm that the electron-dense materials along the S-layer contained nitrogen.

The S-layer in *T. forsythensis* has been suggested to be associated with hemagglutination, adhesion and invasion of host cells; however, its precise

Fig. 5. ESI using three-window method and parallel-EELS for *T. forsythensis* cells incubated in DAB medium with H_2O_2 and DAB. Nitrogen distribution corresponded to the outermost cell surface, the S-layer. a) Zero-loss transmission image. b) Background removed net ΔE_{max} 410 eV. c) Parallel-EELS analysis of the circled area in Fig. 5b. d) The second window of ΔE_{w2} 350 eV. e) The first window of ΔE_{w1} 382 eV of nitrogen. f) ΔE_{max} 410 eV of K edge of nitrogen. g) Superimposed image of nitrogen distribution over the zero-loss image. CM, cytoplasmic membrane; OM, outer membrane; S, S-layer.

functions remain unknown. Sakakibara et al. (2007) suggested that lack of the S-layer had a minor effect on hemagglutination. Moreover, hemagglutination inhibition by S-layer-specific antisera raised against the 230 and/or 270 kDa proteins was almost the same as that produced by the control pre-immune serum. Thus the S-layer seemed to have a marginal association with the hemagglutination. Because thin section microscopy revealed that the cell surfaces of the single mutants ($\Delta 230$ and $\Delta 270$) were partially covered with substances like the S-layer, an abnormal state of the cell surface could hinder hemagglutination. In the double mutant ($\Delta 230-270$), which lacks the S-layer, the putative hemagglutinin might be fully exposed and functioning. By contrast, the S-layer proteins in *T. forsythensis* clearly were responsible for adhesion to the host cells. The S-layer protein-deficient mutants lost adherence almost completely.
