Received 30 June 1987/Accepted 3 November 1987

**A collection of 196 spontaneous mutations in the *SUP4-o* gene of the yeast *Saccharomyces cerevisiae* was analyzed by DNA sequencing. The classes of mutation identified included all possible types of base-pair substitution, deletions of various lengths, complex alterations involving multiple changes, and insertions of transposable elements. Our findings demonstrate that at least several different mechanisms are responsible for spontaneous mutagenesis in *S. cerevisiae*.**

Although spontaneous mutagenesis has been well studied in the yeast *Saccharomyces cerevisiae*, relatively little is known about the molecular nature of spontaneous mutational events or the factors that influence such events in this organism (for reviews, see references 6, 10, and 18). To improve our understanding of mutational mechanisms in *S. cerevisiae*, we recently developed a system in which mutations occurring in the tyrosine suppressor tRNA gene *SUP4-o* can be rapidly analyzed to determine the DNA sequence changes responsible (12). Here we describe our use of the *SUP4-o* system to analyze spontaneous mutations in *S. cerevisiae*.

In this system, *SUP4-o* is carried on the centromere plasmid YCpMP2. Autonomous yeast centromere-containing plasmids mimic the behavior of yeast chromosomes. They are maintained predominantly as single copies in haploid cells (a feature essential for mutant selection), exhibit typical chromatin organization, and replicate once per cell cycle in S phase (2). Forward mutations in the *SUP4-o* gene are detected by their elimination of suppressor activity (13). The haploid yeast strain MKP-o (12) carries ochre-suppressible markers which, in the absence of suppression, confer resistance to the arginine analog canavanine (*can1-100*), cause red pigmentation (*ade2-1*), or result in lysine auxotrophy (*lys2-1*). Cells harboring YCpMP2 are canavanine sensitive and form white, lysine-independent colonies. Loss of suppressor activity leads to the formation of canavanine-resistant, red or pink colonies unable to grow when replicated to lysine omission medium. Following mutant characterization *in vivo*, yeast DNA is isolated and transformed into *Escherichia coli* JF1754 (12) to retrieve the shuttle vector. Then the mutant *SUP4-o* genes are sequenced directly on linearized double-stranded YCpMP2 plasmid DNA by the dideoxynucleotide chain termination technique (17) by the procedure of Korneluk et al. (8).

To isolate independently occurring spontaneous mutants, cultures of MKP-o carrying YCpMP2 were grown to stationary phase (approximately  $1.5 \times 10^7$  cells per ml) in medium selective for the plasmid. Under these conditions, 90% of the cells retain YCpMP2 (12). Cell suspensions were then plated on appropriate medium to select canavanine-resistant colonies. Among the total canavanine-resistant colonies de-

tected, 2.6% (326 of 12,342) were classified as *SUP4-o* mutants (red or pink and Lys<sup>-</sup>). On this basis, the mean *SUP4-o* mutation frequency was determined to be  $2.4 \times 10^{-6}$ , corresponding to a spontaneous mutation rate of  $1.9 \times 10^{-7}$  events per generation (calculated as described previously [12]). A collection of 196 spontaneous *SUP4-o* mutants, each isolated from a separate culture, was characterized by DNA sequencing.

Single base-pair substitutions were recovered at a frequency of  $2.0 \times 10^{-6}$  and accounted for 84% of the spontaneous mutants (Table 1). The rate of mutation was calculated to be  $1.8 \times 10^{-9}$  per base pair per generation. Both types of transition and all four transversions were identified, but there was a slight excess of transversions, and three times as many events occurred at G · C sites as at A · T sites (Table 2). Spontaneous base substitution mutagenesis at the chromosomal *SUP4-o* locus is also biased towards transversions and G · C sites (9), suggesting that the same mutational processes act on the plasmid and chromosomal copies of *SUP4-o*. In addition to single events, we also detected one nontandem, double-base-pair change involving A · T → G · C and G · C → A · T substitutions at positions +12 and +14, respectively. While the spontaneous base-pair substitutions were distributed throughout the *SUP4-o* gene, mutations occurred at three locations (+18, +83, and +88) much more frequently than at others (Fig. 1). No point mutations were detected 5' or 3' to the region encoding *SUP4-o*, and base-pair changes were found at only one position (+51) within the tRNA intron. Outside the intron, spontaneous

TABLE 1. Sequence alterations in spontaneous mutants

Alteration	No. detected (% of mutants examined)	Frequency ( $\times 10^{-6}$ )
Base-pair substitution		
Single change	164 (83.7)	2.01
Double change	1 (0.5)	0.012
Total	165 (84.2)	2.02
Deletion		
Single base pair	10 (5.1)	0.12
Multiple base pairs	6 (3.1)	0.074
Complex event	3 (1.5)	0.036
Total	19 (9.7)	0.23
Ty insertion	12 (6.1)	0.15

FIG. 2. Inverted repeat that potentially can direct the replacement of the sequence 5'-GATCTCA-3' with 5'-CCGGG-3', as diagrammed. The replacement perfects the structure of the palindrome. Only the transcribed strand is shown.

12 inserts with established sequences for delta elements revealed striking homologies (up to 100%). Agarose gel electrophoresis of the 12 mutant plasmids following digestion with *Bam*HI indicated that 11 were larger than YCpMP2 by 6 kilobase pairs, the approximate size of a Ty element (15). Thus, we concluded that each of the 11 contained an intact transposon. The 12th plasmid was just slightly larger than YCpMP2, consistent with the presence of a solo delta sequence. Therefore, the insertion in this plasmid may be the remnant of a transposon that had excised by homologous recombination between its flanking deltas (15, 16). Insertion of Ty elements accounted for 6.1% of the total spontaneous mutants characterized. From this value, the frequency of Ty transposition into *SUP4-o* on the plasmid was calculated to be  $1.5 \times 10^{-7}$ . However, this may be an overestimate because of the apparent hot spot for transposition at +37. Although the factors that promote transposition of Ty are not well understood, insertion generally has been found to occur in A+T-rich sequences (3, 4, 20). Consistent with this observation, Ty integrated at *SUP4-o* sites in regions of high A · T pair density.

In summary, we analyzed a collection of 196 mutations arising spontaneously in the *SUP4-o* gene of *S. cerevisiae*. Several classes of mutation were detected, pointing to the complexity of spontaneous mutagenesis in *S. cerevisiae*. Furthermore, certain of these results support the hypothesis (5) that DNA sequence-directed events may generate spontaneous mutations in eucaryotic cells.

We thank S. Butland, K. Nyman, and L. Pillon for technical assistance, B. Triggs-Raine and G. B. Golding for computer analyses of the delta sequences and potential secondary structures, respectively, J. W. Drake, H. B. LeJohn, and P. C. Loewen for their critical reading of the manuscript, and S. Berg for typing the manuscript.

S.B. and K.N. were supported in part by a grant from the E. I. Canada Challenge '86 program to B.A.K. This work was supported by the Natural Sciences and Engineering Research Council of Canada.
