ABSTRACT

Experiments with intact plants of *Lolium perenne* previously grown with ¹⁴NO₃⁻ revealed significant efflux of this isotopic species when the plants were transferred to solutions of highly enriched ¹⁵NO₃⁻. The exuded ¹⁴NO₃⁻ was subsequently reabsorbed when the ambient solutions were not replaced. When they were frequently replaced, continual efflux of the ¹⁴NO₃⁻ was observed. Influx of ¹⁵NO₃⁻ was significantly greater than influx of ¹⁴NO₃⁻ from solutions of identical NO₃⁻ concentration. Transferring plants to ¹⁴NO₃⁻ solutions after a six-hour period in ¹⁵NO₃⁻ resulted in efflux of the latter. Presence of Mg²⁺, rather than Ca²⁺, in the ambient ¹⁵NO₃⁻ solution resulted in a decidedly increased rate of ¹⁴NO₃⁻ efflux and a slight but significant increase in ¹⁵NO₃⁻ influx. Accordingly, net NO₃⁻ influx was slightly depressed. A model in accordance with these observations is presented; its essential features include a passive bidirectional pathway, an active uptake mechanism, and a pathway for recycling of endogenous NO₃⁻ within unstirred layers from the passive pathway to the active uptake site.

Under appropriate experimental conditions, efflux of a range of plant tissue components has been noted even in the absence of metabolic stress (2, 4-6, 8, 13, 14, 21, 25), but evidence for NO₃⁻ efflux is quite limited. When wheat seedlings were exposed sequentially to ¹⁵NO₃⁻ and ¹⁴NO₃⁻, Ashley (1) failed to recover in the tissue all of the ¹⁵NO₃⁻ previously removed from the solution. His data indicate that about one-fourth of the absorbed ¹⁵NO₃⁻ may have been lost from the roots during exposure to ¹⁴NO₃⁻. Net loss of NO₃⁻ to ambient solution has been observed when plants previously cultured on NO₃⁻ were placed in NO₃⁻-free solutions (15, 16). These results suggest that continuous NO₃⁻ efflux may be a common feature of net NO₃⁻ uptake by roots of higher plants.

In general, ion efflux studies have focused on the process itself rather than on the possible relationship between concurrent efflux and ion accumulation by plants. The present paper reports results from experiments conducted (a) to establish the NO₃⁻ efflux properties of intact perennial ryegrass seedlings and (b) to examine the relationship between NO₃⁻

adsorption and NO₃⁻ efflux in those seedlings. Use of NO₃⁻ highly enriched with ¹⁵N permitted direct measurement of the simultaneously occurring fluxes. The results obtained are in agreement with a proposed NO₃⁻ uptake mechanism whose essential features include: (a) an active influx mechanism, (b) a passive, bidirectional pathway dependent only on diffusion and concentration gradients, and (c) an internal pathway for NO₃⁻ recycling.

MATERIALS AND METHODS

Experiment 1. Perennial ryegrass (*Lolium perenne*) seeds were surface sterilized in 5% H₂O₂ and germinated in opaque polyethylene cups with bottoms of stainless steel screen. After thinning, each cup (one culture) contained about 45 seedlings. Plants were grown in a chamber for 21 days at 22 ± 1 C during the light period (16 hr, 238 hlx) and 18 ± 1 C during darkness. Four cultures were placed in containers of 820 ml solution, containing 0.1 mM KH₂PO₄, 0.25 mM Ca(¹⁴NO₃)₂, 0.25 mM MgSO₄, 1 mg of Fe as FeEDTA, and other trace elements supplied at one-fifth those in Hoagland's solution (10). Solutions were replaced every other day, and on the 19th day the Ca(NO₃)₂ was doubled. On the 21st day, the nutrient solutions were removed, the roots were rinsed with a strong jet of distilled water, and then in 10 changes of distilled water. After draining thoroughly, the plants were exposed to solutions containing 0.75 mM Ca(¹⁵NO₃)₂ or Mg(¹⁵NO₃)₂ with a ¹⁵N enrichment of 97.5 atom %. Duplicate containers were harvested after 3, 6, 12, and 18 hr of continuous illumination (238 hlx) at 24 ± 1 C. The solutions were analyzed for total NO₃⁻ by ultraviolet absorption at 207 nm (3). The quantities of NO₂⁻ in the solutions were not sufficiently high to contribute significantly to absorbance, and absence of other ultraviolet-absorbing components was confirmed by spectral scanning. The atom per cent ¹⁵N of all solutions was determined mass spectrometrically (23) following reduction of NO₃⁻ to NH₃ using Devarda's alloy. Solution NO₂⁻ was measured using equal volumes of 1% sulfanilamide in 3 N HCl and 0.01% N-(1-naphthyl)-ethylenediamine dihydrochloride. Ninhydrin-reactive amino nitrogen (before and after refluxing in 6 N HCl for 16 hr) was determined by the method of Yemm and Cocking (26).

Experiment 2. Perennial ryegrass plants were grown essentially as in experiment 1. On the day of the experiment, each culture was mounted in an opaque, 60-ml leaching funnel. A stopcock permitted rapid removal of the continuously aerated solutions (55 ml) as desired. Each of the four treatments consisted of six replications of these single culture assemblies. The experiment was conducted at 70.2 hlx and 23 ± 1 C. Prior to imposition of the treatments, all cultures received a pretreatment (initiated 1 hr after onset of the dark period) of 0.75 mM Ca(¹⁴NO₃)₂, pH 5.0, for 3 hr. These solutions were then replaced with the appropriate treatment solutions after

thoroughly rinsing the roots. The four treatments consisted of $\text{Ca}^{(14)\text{NO}_3)_2}$, $\text{Mg}^{(14)\text{NO}_3)_2}$, $\text{Ca}^{(15)\text{NO}_3)_2}$, and $\text{Mg}^{(15)\text{NO}_3)_2}$, each 0.75 mM, pH 5.0. The ^{15}N enrichment of the latter two salts was 97.5 atom %. At 1-hr intervals the solutions were withdrawn and stored under refrigeration. The roots were again rinsed and fresh volumes of the same treatment solutions were introduced into the funnels. The sequence of root exposure, solution withdrawal, washing, and solution replenishment was repeated six times.

Solution analyses were conducted as described for experiment 1. The various NO_3^- fluxes ($^{14}\text{NO}_3^-$ influx, $^{15}\text{NO}_3^-$ influx, $^{14}\text{NO}_3^-$ efflux, and $^{15}\text{NO}_3^-$ efflux) were calculated as the difference in the amount of each nitrogen species present in solution at the start and end of each hourly period.

Experiment 3. Perennial ryegrass was grown similarly to the first two experiments except that temperature was 27 ± 1 C during the light period and the light intensity was slightly less (205 hlx). In addition, the $\text{Ca}^{(14)\text{NO}_3)_2}$ in the nutrient solution was increased to 0.5 mM, 24 hr before initiation of the experiment. The experimental techniques were similar to those of experiment 2 and consisted of two phases (6 hr each) after all cultures had been pretreated for 3 hr in 0.7 mM $\text{Ca}^{(14)\text{NO}_3)_2}$. The sequence of events for the three treatments is shown in Table I. Light intensity was 157 hlx, and temperature was 25 ± 1 C throughout. Solution analyses were as described for experiment 1.

Table I. *Isotopic NO_3^- Treatment Designations Employed in Experiment 3*

Numerical values refer to concentrations in meq l^{-1} . Initial pH was 5.0, and all solutions were changed hourly during the treatment period.

Treatment No.	Pretreatment Period	Treatment Period	
		Phase A ¹	Phase B ²
	0-3 hr	3-9 hr	9-15 hr
1	1.4 $\text{Ca}^{(14)\text{NO}_3)_2}$	1.4 $\text{Ca}^{(14)\text{NO}_3)_2}$	1.4 $\text{Ca}^{(15)\text{NO}_3)_2}$ ³
2	1.4 $\text{Ca}^{(14)\text{NO}_3)_2}$	1.4 $\text{Ca}^{(15)\text{NO}_3)_2}$ ³	1.4 $\text{Ca}^{(14)\text{NO}_3)_2}$
3	1.4 $\text{Ca}^{(14)\text{NO}_3)_2}$	2.8 $\text{Ca}^{(15)\text{NO}_3)_2}$ ³	2.8 $\text{Ca}^{(14)\text{NO}_3)_2}$

¹ Replications were eight, nine, and nine for treatments 1, 2, and 3, respectively.

² All treatments had six replications.

Following hydrolysis	$\text{Ca}^{(15)\text{NO}_3)_2}$	17	16	15	64
	$\text{Mg}^{(15)\text{NO}_3)_2}$	23	33	49	133

The data of all three experiments are expressed per g dry weight (70 C) of the root tissue.

RESULTS

The time course of $^{14}\text{NO}_3^-$ efflux during $^{15}\text{NO}_3^-$ uptake from solutions of $\text{Ca}^{(15)\text{NO}_3)_2}$ or $\text{Mg}^{(15)\text{NO}_3)_2}$ in experiment 1 is shown in Figure 1. Sizeable amounts of $^{15}\text{NO}_3^-$ were absorbed during the periods when $^{14}\text{NO}_3^-$ appeared in the external solution. Cumulative values for $^{15}\text{NO}_3^- \text{N}$ absorbed ($\mu\text{g } ^{15}\text{N g}^{-1}$ roots, dry weight) after 3-, 6-, 12-, and 18-hr were 2410, 5520, 10,360, and 13,000 for the $\text{Ca}^{(15)\text{NO}_3)_2}$ treatment and 2080, 5490, 8840, and 12,700 for the $\text{Mg}^{(15)\text{NO}_3)_2}$ treatment. Both solutions were completely depleted of NO_3^- between 12 and 18 hr. Maximal $^{14}\text{NO}_3^-$ efflux was observed at 3 hr and was 40% greater to $\text{Mg}^{(15)\text{NO}_3)_2}$ than to $\text{Ca}^{(15)\text{NO}_3)_2}$ (Fig. 1). After 3 hr, however, the amount of $^{14}\text{NO}_3^-$ in each solution declined, indicating reabsorption of exuded $^{14}\text{NO}_3^-$. Total reabsorption had occurred by 18 hr. Exudation of NO_2^- (Table II) and of ninhydrin-reactive constituents (Table III) also occurred but the quantities of these components recovered in solution were small compared to the magnitude of $^{14}\text{NO}_3^-$ efflux (Fig. 1).

Replacement of the original solutions at hourly intervals in the second experiment permitted a more critical examination of the various NO_3^- fluxes. At the end of each hourly period, a decrease in the ^{15}N -enrichment of the $\text{Ca}^{(15)\text{NO}_3)_2}$ and $\text{Mg}^{(15)\text{NO}_3)_2}$ solutions from their initial value of 97.5% was found, and appropriate calculations revealed significant and continual $^{14}\text{NO}_3^-$ efflux to the $^{15}\text{NO}_3^-$ solutions (Figs. 2 and 3). Cumulative $^{15}\text{NO}_3^-$ influx, the best estimate of NO_3^- uptake capacity, substantially exceeded $^{14}\text{NO}_3^-$ influx with both Ca^{2+} and Mg^{2+} salts (Figs. 2 and 3). These differences were clearly evident within the 1st hr. After 6-hr exposure to $\text{Ca}^{(15)\text{NO}_3)_2}$, cumulative $^{15}\text{NO}_3^-$ influx reached 9.2 mg $^{15}\text{N g}^{-1}$ roots, whereas only 5.7 mg $^{14}\text{N g}^{-1}$ roots were taken up from $\text{Ca}^{(14)\text{NO}_3)_2}$ (Fig. 2). Throughout the experiment $^{14}\text{NO}_3^-$ influx from both $\text{Ca}^{(15)\text{NO}_3)_2}$ and $\text{Mg}^{(15)\text{NO}_3)_2}$ occurred at only 60 to 65% of the capacity of the roots for NO_3^- uptake as estimated from $^{15}\text{NO}_3^-$ influx. Influx of $^{15}\text{NO}_3^-$ was slightly larger from $\text{Mg}^{(15)\text{NO}_3)_2}$ than from $\text{Ca}^{(15)\text{NO}_3)_2}$ (Figs. 2 and 3).

FIG. 2. Time course of cumulative NO_3^- influx and efflux by seedlings during exposure to solutions of $\text{Ca}^{(15}\text{NO}_3)_2$ or $\text{Ca}^{(14}\text{NO}_3)_2$ in experiment 2.

FIG. 3. Time course of cumulative NO_3^- influx and efflux by seedlings during exposure to solutions of $\text{Mg}^{(15}\text{NO}_3)_2$ or $\text{Mg}^{(14}\text{NO}_3)_2$ in experiment 2.

Efflux of $^{14}\text{NO}_3^-$ to $\text{Ca}^{(15}\text{NO}_3)_2$ solutions was also observed in experiment 3. The higher ambient $^{15}\text{NO}_3^-$ concentration elicited a more rapid $^{14}\text{NO}_3^-$ efflux during phase A (Fig. 4). Seedlings which had been exposed to 1.4 meq $\text{Ca}^{(14}\text{NO}_3)_2$ l^{-1} for a total of 9 hr (treatment I, phase B) prior to exposure to $\text{Ca}^{(15}\text{NO}_3)_2$ exuded more $^{14}\text{NO}_3^-$ than those receiving only the 3-hr pretreatment (treatment II, phase A).

Following absorption from $\text{Ca}^{(15}\text{NO}_3)_2$ solutions containing either 1.4 meq l^{-1} or 2.8 meq l^{-1} , $^{15}\text{NO}_3^-$ efflux to $^{14}\text{NO}_3^-$ solutions was also demonstrated (Fig. 5). The $^{15}\text{NO}_3^-$ efflux rate was greater at the higher concentration of $^{14}\text{NO}_3^-$ in the ambient solution.

DISCUSSION

Proposed Model for NO_3^- Uptake. It is necessary to account for the simultaneous occurrence of the influx and efflux

phenomena observed in these experiments. Based in part on the model proposed by Oertli (20) in describing the absorption isotherm for Rb^+ uptake, a schematic representation of a proposed mechanism for NO_3^- uptake is shown in Figure 6. The salient features of the proposed mechanism are:

1. A NO_3^- pumping mechanism (P) located at the outer unstirred layer-plasmalemma interface, the operation of which is dependent on aerobic metabolism (9, 11, 19). No specific type of active mechanism is assigned to the pump. It is, however, assumed to be inwardly directed only and is, therefore, shown as a diode. It is assumed that P operates at, or close to, its maximal capacity.
2. A passive leak mechanism whose exit (or entry) through

FIG. 4. Time course of cumulative $^{14}\text{NO}_3^-$ efflux to $\text{Ca}^{(15}\text{NO}_3)_2$ solutions of two concentrations, experiment 3. The open squares are for seedlings that had absorbed $^{14}\text{NO}_3^-$ under the exact conditions of the experiment for 6 hr prior to exposure to $^{15}\text{NO}_3^-$ (Table I).

FIG. 5. Time course of cumulative $^{15}\text{NO}_3^-$ efflux to $\text{Ca}^{(14}\text{NO}_3)_2$ solutions of two concentrations following a previous 6-hr exposure to $^{15}\text{NO}_3^-$, experiment 3 (Table I).

the plasmalemma (M) is designated L. The leak may function either toward the ambient solution (S) or the cytoplasm (C), depending on the direction of the concentration gradient existing between the internal and external surfaces of the plasmalemma. The bidirectional nature of the leak seems justified since on the one hand, passive NO₃⁻ influx has been previously reported (11, 19) while on the other, efflux in general is a common feature of ion-root relationships (cf. "Introduction"). It is envisaged that L and P are quite adjacent, each representing areas along the plasmalemma which may, in fact, overlap. For an individual root cell, a number of such L-P associations exist.

3. A recycling pathway along which NO₃⁻ diffusion from the cytoplasm (via L) to P may occur.

4. An outer (O) and inner (I) unstirred layer whose physical and chemical characteristics are quite different from those of the solution (S) and cytoplasm (C) with which they are in contact (7).

5. A series of resistances (R) indicated by subscripts referring to the regions within which the resistances are operative. It is assumed that the magnitude of the various resistances to NO₃⁻ diffusion is the same for all isotopes of the same ion and that R_o is greater than R_{1p}.

The fate of exogenous NO₃⁻ on entry into root cells is also indicated in Figure 6 and, at any instant, the NO₃⁻ concentration within the root cytoplasm is the net result of the indicated reaction sequence. Passive NO₃⁻ fluxes in the root-solution system, then, are postulated to arise from the NO₃⁻ concentration gradients between (a) C and L, (b) L and P, and (c) L and S.

Application of Model. In this section, the proposed model for NO₃⁻ uptake is applied to the results obtained. The following definitions and nomenclature apply: (a) [X]_l, [X]_p, [X]_s, or [X]_c = the concentration of X at L, P, S, and C respectively, where X represents either ¹⁴NO₃⁻ or ¹⁵NO₃⁻; (b) leakage = diffusion of ¹⁴NO₃⁻ or ¹⁵NO₃⁻ from C to L; (c) recycling = diffusion of ¹⁴NO₃⁻ or ¹⁵NO₃⁻ from L to P; (d) efflux = diffusion of ¹⁴NO₃⁻ or ¹⁵NO₃⁻ from L to S; (e) hence, efflux = leakage - recycling.

FIG. 6. A generalized model for NO₃⁻ uptake by root cells and possibilities for NO₃⁻ reaction within the cytoplasm: S = solution; O = outer unstirred layer; M = plasmalemma; I = inner unstirred layer; C = cytoplasm.

The plants were grown in ¹⁴NO₃⁻ so [¹⁵NO₃⁻]_p and [¹⁵NO₃⁻]_c may be assumed to have been vanishingly low when they were first exposed to the treatment solutions. On the other hand, [¹⁴NO₃⁻]_c would be high and greater than [¹⁴NO₃⁻]_p. Upon exposure to the Ca(¹⁴NO₃)₂ or Mg(¹⁴NO₃)₂ treatments of experiment 2, ¹⁴NO₃⁻ would diffuse from S to P. Simultaneously there would be occurring leakage of ¹⁴NO₃⁻ from C to L ([¹⁴NO₃⁻]_c > [¹⁴NO₃⁻]_l) and a recycling of these leaked ¹⁴NO₃⁻ ions to P since R_o > R_{1p}. If, as a result, ¹⁴NO₃⁻ accumulated at P, a restriction in the diffusion rate of ¹⁴NO₃⁻ from S to P would develop, leading to a lower ¹⁴NO₃⁻ influx rate than had previously been the case. In this view the ¹⁴NO₃⁻ influx rate would be directly or indirectly dependent on (a) the extent of recycling and (b) the activity of the absorption mechanism (P). In contrast, when roots were exposed to ¹⁵NO₃⁻ solutions, [¹⁵NO₃⁻]_p would be essentially nil while the initial [¹⁴NO₃⁻]_p would have been finite, since it was being supplied continuously from endogenous ¹⁴NO₃⁻ via the leak and recycling pathway. Hence, in response to a ¹⁵NO₃⁻ concentration gradient considerably greater than that of ¹⁴NO₃⁻, the diffusive flux of ¹⁵NO₃⁻ from S to P would be greater than that of ¹⁴NO₃⁻ from an otherwise identical ambient solution (Figs. 2 and 3).

The appearance of ¹⁴NO₃⁻ in solution on exposure to ¹⁵NO₃⁻ in experiments 1 and 2 (Figs. 1, 2, and 3) and the subsequent reabsorption of the previously exuded ¹⁴NO₃ after the 3rd hr when the ambient solution was not continually replaced (Fig. 1) are consistent with the proposed mechanism. As ¹⁵NO₃⁻ influx continued, ¹⁴NO₃⁻ and ¹⁵NO₃⁻ would leak from C to L in proportion to their respective concentration gradients between the inner surface of the plasmalemma and L. Because of the presence of the inner unstirred layer (I) complete mixing of ¹⁵NO₃⁻ with ¹⁴NO₃⁻ in the cytoplasm need not occur prior to its diffusion to L.

In the early stages, ¹⁴NO₃⁻ would be the dominant species undergoing leakage since [¹⁴NO₃⁻]_c would be high and [¹⁵NO₃⁻]_c low. As the endogenous ¹⁴NO₃⁻ accessible to the leakage channels became depleted during continual exposure to ¹⁵NO₃⁻ (through enzymatic reduction, translocation, transport to vacuoles, or prior efflux), ¹⁴NO₃⁻ leakage and recycling would decline. In plants for which the ambient solutions were not continually replaced, the diffusion gradients ultimately would shift such that the ¹⁴NO₃⁻ which had previously exuded to the external solution would subsequently diffuse back again either to P or through the leakage channels into the cytoplasm (Fig. 1). Since [¹⁴NO₃⁻]_s was minimized in experiment 2 by periodically replacing the Ca(¹⁵NO₃)₂ and Mg(¹⁵NO₃)₂ solutions, ¹⁴NO₃⁻ efflux would continue to occur (Figs. 2 and 3). Nonetheless, it appears that the amount of endogenous ¹⁴NO₃⁻ available for efflux was approaching depletion as evidenced by the decrease in rates of ¹⁴NO₃⁻ efflux.

The greater rate of ¹⁴NO₃⁻ efflux to the higher concentration of ¹⁵NO₃⁻ during phase A (Fig. 4) and the greater rate of ¹⁵NO₃⁻ efflux to the higher concentration of ¹⁴NO₃⁻ during phase B (Fig. 5) of experiment 3 also support the proposed model in that the higher ambient solution concentrations should result in a greater proportion of the ambient isotopic species (relative to those undergoing leakage from the cytoplasm) at P. Hence, a greater tendency should exist for the tissue ions to continue to diffuse to the external solution.

Curvilinearity of the Fluxes. Prediction equations for the cumulative values of each flux over the 6-hr period were computed for experiment 2. All patterns obeyed quadratic functions of the type $y = a + bt + ct^2$ where y = cumulative uptake and t = time in hours. As noted by the R² values in Figures 2 and 3, the prediction equations described the data quite accurately. For each individual set of observations, the

use of orthogonal polynomials resulted in independent linear and quadratic coefficients, thus permitting direct comparison of coefficients in any two equations. A consequence of the number of time variables employed (*i.e.*, seven) and of the use of orthogonal polynomials was that the linear coefficients reflect the slopes of the curves at 3 hr. The relative magnitudes of the linear and quadratic coefficients are presented in Table IV. The linear component of NO₃⁻ uptake is envisaged to be that rate which would obtain if absorption occurred from a NO₃⁻ pool into a sink whose components did not limit the uptake rate; an attendant assumption here is that ambient NO₃⁻ concentrations not be depleted in such a way that they become rate-limiting. In this view, linear rates reflect the capacity of the tissue to absorb either ¹⁴NO₃⁻ or ¹⁵NO₃⁻. It is seen in Table IV that such capacity was smaller for ¹⁴NO₃⁻ uptake than for ¹⁵NO₃⁻ uptake whether the ambient cation was Ca²⁺ or Mg²⁺. In contrast, the quadratic components for ¹⁴NO₃⁻ influx tended to exceed those for ¹⁵NO₃⁻ influx.

It is unlikely that the quadratic nature of the influx patterns (Figs. 2 and 3) resulted from progressively limiting ambient NO₃⁻ concentration because the removal of solution ¹⁵NO₃⁻ never exceeded 12% of that originally offered. We suggest that the progressively decreasing rate of influx was due to increased recycling. Alternatively, the experimental conditions may have resulted in an impairment of the absorption mechanism after about 2 hr, although we have no reason to expect this to have happened.

Effect of Ambient Cation. Figure 7, combines the ¹⁵NO₃⁻ influx and ¹⁴NO₃⁻ efflux for the Ca(¹⁵NO₃)₂ and Mg(¹⁵NO₃)₂ treatments shown in Figures 2 and 3. Also included in Figure 7 is net NO₃⁻ influx (¹⁵NO₃⁻ influx minus ¹⁴NO₃⁻ efflux) for the two treatments. The relative sizes of the coefficients of these fluxes are shown in Table V. Although the patterns with the two divalent cations were very similar (Fig. 7), ¹⁵NO₃⁻ influx in the presence of Mg²⁺ significantly exceeded that in the presence of Ca²⁺. This stimulation arose from enhanced linear uptake only (Table 5) and is consistent with the general observation of enhanced anion uptake from single salt solutions containing a rapidly absorbed cation *versus* a slowly absorbed cation. In this context Mg²⁺ is commonly absorbed by roots more rapidly than Ca²⁺ (12, 17). Moreover, results of experiments to be published elsewhere showed that ²⁸Mg²⁺ was absorbed more rapidly than ⁴⁵Ca²⁺ by ryegrass plants similar to those used here.

The largest effect of cation moiety was on ¹⁴NO₃⁻ efflux which was stimulated substantially when Mg²⁺, rather than Ca²⁺, was the counter ion (Figs. 1 and 7; Table V). The direct consequence of this Mg²⁺-stimulated ¹⁴NO₃⁻ efflux was to depress the net influx of NO₃⁻ from Mg(¹⁵NO₃)₂ compared to Ca(¹⁵NO₃)₂ (Fig. 7, Table V).

Table IV. Comparison of Linear and Quadratic Coefficients of ¹⁴NO₃⁻ Influx from Ca²⁺ or Mg²⁺ Salts with Those of ¹⁵NO₃⁻ Influx

Experiment 2, linear comparisons refer to the 3rd hour.

Comparison	Ambient Cation	Relationship	
		Linear coefficient	Quadratic coefficient

FIG. 7. Time course of cumulative NO₃⁻ influx and efflux by seedlings during exposure to solutions of Ca(¹⁵NO₃)₂ (open symbols) and Mg(¹⁵NO₃)₂ (closed symbols), experiment 2. Influx of ¹⁵NO₃⁻ and efflux of ¹⁴NO₃⁻ are replotted from Figures 2 and 3; net NO₃⁻ influx is calculated as the difference between these two values.

Table V. Comparison of the Linear and Quadratic Coefficients of NO₃⁻ Influx and Efflux as Affected by Ambient Cation Experiment 2, linear comparisons refer to the 3rd hour.

Flux Parameter	Relationship	
	Linear coefficient	Quadratic coefficient
¹⁵ NO ₃ ⁻ influx	Mg ²⁺ > Ca ²⁺ *	NS
Net influx†	Ca ²⁺ > Mg ²⁺ **	NS
¹⁴ NO ₃ ⁻ influx	NS	NS
¹⁴ NO ₃ ⁻ efflux	Mg ²⁺ > Ca ²⁺ **	NS

† Net influx = ¹⁵NO₃⁻ influx - ¹⁴NO₃⁻ efflux (to the ¹⁵NO₃⁻ solution).

* P ≤ 0.10.
** P ≤ 0.01.

The fact that cumulative ¹⁴NO₃⁻ efflux, as well as amino-N efflux, were restricted by the presence of ambient Ca²⁺ relative to Mg²⁺ (Fig. 1 and 7; Table III) suggests decreased membrane permeability in the presence of Ca²⁺ (22, 24). However, it is also possible that the enhanced ¹⁴NO₃⁻ efflux in the absence of ambient Ca²⁺ resulted from a more favorable ¹⁴NO₃⁻ concentration gradient between the cytoplasm and the solution. Such a situation could arise if ambient Mg²⁺ compared to ambient Ca²⁺ resulted in a relatively greater accumulation of ¹⁴NO₃⁻ in the root tissue (18).

Acknowledgments—We extend our thanks to Dr. L. A. Nelson for valuable assistance in the statistical treatment of the data. The senior author would also like to express his appreciation for a W. K. Kellogg Foundation Fellowship during the initial stages of these investigations.
