

# Transient Transcriptional Regulation of the *CYS-C1* Gene and Cyanide Accumulation upon Pathogen Infection in the Plant Immune Response<sup>1[C][W]</sup>

Irene García\*, Tábata Rosas, Eduardo R. Bejarano, Cecilia Gotor, and Luis C. Romero

Instituto de Bioquímica Vegetal y Fotosíntesis, Consejo Superior de Investigaciones Científicas and Universidad de Sevilla, E-41092 Sevilla, Spain (I.G., C.G., L.C.R.); and Instituto de Hortofruticultura Subtropical y Mediterránea "La Mayora," Departamento de Genética, Facultad de Ciencias, Universidad de Málaga, E-29071 Malaga, Spain (T.R., E.R.B.)

Cyanide is produced concomitantly with ethylene biosynthesis. *Arabidopsis* (*Arabidopsis thaliana*) detoxifies cyanide primarily through the enzyme  $\beta$ -cyanoalanine synthase, mainly by the mitochondrial CYS-C1. CYS-C1 loss of function is not toxic for the plant and leads to an increased level of cyanide in *cys-c1* mutants as well as a root hairless phenotype. The classification of genes differentially expressed in *cys-c1* and wild-type plants reveals that the high endogenous cyanide content of the *cys-c1* mutant is correlated with the biotic stress response. Cyanide accumulation and CYS-C1 gene expression are negatively correlated during compatible and incompatible plant-bacteria interactions. In addition, *cys-c1* plants present an increased susceptibility to the necrotrophic fungus *Botrytis cinerea* and an increased tolerance to the biotrophic *Pseudomonas syringae* pv *tomato* DC3000 bacterium and *Beet curly top virus*. The *cys-c1* mutation produces a reduction in respiration rate in leaves, an accumulation of reactive oxygen species, and an induction of the alternative oxidase *AOX1a* and pathogenesis-related *PR1* expression. We hypothesize that cyanide, which is transiently accumulated during avirulent bacterial infection and constitutively accumulated in the *cys-c1* mutant, uncouples the respiratory electron chain dependent on the cytochrome *c* oxidase, and this uncoupling induces the alternative oxidase activity and the accumulation of reactive oxygen species, which act by stimulating the salicylic acid-dependent signaling pathway of the plant immune system.

The gaseous hormone ethylene is known to regulate multiple physiological and developmental processes in plants, such as seedling emergence, leaf and flower senescence, climacteric fruit ripening, and organ abscission. Ethylene is also involved in the response of plants to abiotic and biotic stresses (Wang et al., 2002; Broekaert et al., 2006; van Loon et al., 2006). Enhanced ethylene production is an early, active response of plants to the perception of pathogen attack and is associated with the induction of defense reactions. During ethylene biosynthesis, *S*-adenosyl-L-Met is converted to 1-aminocyclopropane-1-carboxylic acid (ACC) by ACC synthase. ACC is finally oxidized by ACC oxidase to form ethylene, carbon dioxide, and cyanide (Hartley et al., 1998; Wang et al., 2002). Hydrogen

cyanide is a colorless and highly volatile liquid. The anion cyanide is toxic and renders the cells of an organism unable to use oxygen, primarily through the chelation of divalent and trivalent metal ions in the prosthetic groups of several metalloenzymes, including copper/zinc superoxide dismutase, catalase, nitrate and nitrite reductase, nitrogenase, peroxidases, and the mitochondrial cytochrome *c* oxidase (Isom and Way, 1984; Donato et al., 2007).

Cyanide must be rapidly detoxified and metabolized by the plant to keep the concentration below toxic levels. Plants detoxify cyanide primarily through the enzyme  $\beta$ -cyanoalanine synthase (CAS), for which considerable levels of activity are constitutively found in many plant species. Rhodanese and mercaptopyruvate sulfurtransferase activities also make minor contributions to the cyanide detoxification process (Miller and Conn, 1980). CAS is a pyridoxal phosphate-dependent enzyme that converts Cys and cyanide to hydrogen sulfide and  $\beta$ -cyanoalanine, which is later converted to Asn, Asp, and ammonia by NIT4 class nitrilases (Piotrowski, 2008). *Arabidopsis* (*Arabidopsis thaliana*) plants carry the mitochondrial CAS CYS-C1 (At3g61440; Watanabe et al., 2008), which belongs to the family of  $\beta$ -substituted Ala synthase enzymes. The family also includes the three major *O*-acetyl-serine (thiol)lyase enzymes OAS-A1 (At4g14880), OAS-B (At2g43750), and OAS-C (At3g59760; Watanabe et al., 2008), the L-Cys desulfhydrase DES1 (At5g28030;

Álvarez et al., 2010), the *S*-sulfocysteine synthase CS26 (At3g03630; Bermúdez et al., 2010), and the functionally unknown cytosolic isoforms CYS-D1 (At3g04940) and CYS-D2 (At5g28020). Mutations in CYS-C1 result in plants that accumulate cyanide and that display abnormal root hair (García et al., 2010), suggesting that cyanide has a signaling role in root development. The lack of the mitochondrial *O*-acetyl-serine(thiol)lyase isoform OAS-C, which is necessary to detoxify the sulfide released by the CAS activity, causes an accumulation of sulfide and cyanide and a root phenotype similar to the *cys-c1* loss-of-function mutant (Álvarez et al., 2012b).

Several authors have suggested that cyanide could act as a regulator of other metabolic processes in addition to performing the described role in plant root development (Siegien and Bogatek, 2006). It has been observed that this molecule is released during seed germination and that exogenously applied hydrogen cyanide breaks seed dormancy in several plants (Cohn and Hughes, 1986; Fol et al., 1989; Bogatek et al., 1991; Bethke et al., 2006). The role of cyanide as a regulatory molecule is not restricted to plants, and it has been demonstrated that cyanide is generated in leukocytes from Gly via a peroxidase (Stelmaszyńska, 1986) as well as in the central nervous system, where it has been hypothesized to act as a neuromodulator (Gunasekar et al., 2000; Cipollone and Visca, 2007). Cyanide production can be stimulated by opiates and decreased by treatment with muscarinic receptor agonists (Borowitz et al., 1997; Gunasekar et al., 2004).

Despite the variety of known functions for cyanide in different organisms, the role of cyanide production in plants seems to have been unevaluated to date. In cyanogenic plants, cyanide is produced during the degradation of cyanogenic lipids and from the catabolism of cyanogenic glycosides (Poulton, 1990). Cyanide and cyanogenic compounds play an important role in plant defense against herbivores (Zagrobelyny et al., 2008). In noncyanogenic plants, cyanide is a coproduct of ethylene biosynthesis. The molecule is also produced during the biosynthesis of camalexin, a phytoalexin formed in *Arabidopsis* plants upon infection by a large variety of microorganisms, including bacteria, fungi, and oomycetes (Glawischnig, 2007). During camalexin biosynthesis, the Trp-derived intermediate indole-3-acetonitrile is conjugated with Cys and serves as a substrate for the cytochrome P450 enzyme CYP71B15. This enzyme catalyzes the formation of the thiazoline ring as well as the release of cyanide and subsequent oxidative decarboxylation of dihydrocamalexin acid to camalexin (Glawischnig, 2007; Böttcher et al., 2009). Since both cyanide sources, camalexin and ethylene, are produced after pathogen attack, cyanide should be produced at significant levels during the plant response to pathogens. It has been shown that exogenous cyanide can enhance the resistance of tobacco (*Nicotiana tabacum*) and *Arabidopsis* leaves to *Tobacco mosaic virus* and *Turnip vein clearing virus*, respectively (Chivasa and Carr, 1998; Wong et al., 2002). Recently, it has been demonstrated

that exogenously applied cyanide increases the resistance of young rice (*Oryza sativa*) plants to blast fungus infection, suggesting that cyanide rather than ethylene contributes to plant resistance (Seo et al., 2011).

This work aims to further investigate the role of endogenously produced cyanide in the plant immune response by analyzing the behavior of *Arabidopsis* knockout mutants of the mitochondrial CAS CYS-C1 and the regulation of CYS-C1 in response to pathogen attack.

## RESULTS

### The *cys-c1* Mutant Transcriptome Shows a High Correlation with Biotic Stresses

The loss of function of the CYS-C1 enzyme has previously been characterized in root tissues, but its function in leaves has not been studied to date (García et al., 2010). Phenotypic analysis of the *cys-c1* null mutant shows no obvious alterations in the aerial parts of the plant whether grown in long- or short-day photoperiods. To analyze the effect of the loss of function of the CYS-C1 enzyme at the molecular level, we performed a comparative transcriptomic analysis of leaves of *cys-c1* and wild-type plants grown under identical long-day conditions on Murashige and Skoog (MS) medium for 14 d. Total RNA was prepared and analyzed using the Affymetrix *Arabidopsis* ATH1 GeneChip array. Three biological replicates were performed for each genotype. Restricting the analysis to the genes whose expression was changed at least 2-fold as a threshold and at a significance level of  $P < 0.05$ , we identified 51 genes that exhibited alterations in transcription level. Among them, 31 genes were up-regulated in the *cys-c1* mutant plant compared with the wild-type plant, and 20 genes were down-regulated (Microarray Gene Expression Omnibus database accession no. GSE19242; Supplemental Table S1). To detect physiologically relevant patterns, the genes with altered expression were assigned to functional categories based on classification by the Bio-Array Resource for *Arabidopsis* Functional Genomics (Toufighi et al., 2005). The resulting group lists revealed that a high proportion of both up- and down-regulated genes in the *cys-c1* mutant were associated with the plant's responses to biotic and abiotic stress and signaling (Supplemental Fig. S1). The induction of selected genes such as *WRKY33* (encoding a WRKY transcription factor), *ERF6* (encoding an ethylene response transcription factor), *CYP81F2* (encoding a cytochrome P450 involved in glucosinolate biosynthesis), and *GSTU24* (coding for a putative glutathione-*S*-transferase) was confirmed by real-time reverse transcription (RT)-PCR, thus validating the data obtained by the array (Supplemental Fig. S2).

A meta-analysis of the *cys-c1* transcript profile data was performed by comparison with the available Affymetrix *Arabidopsis* ATH1 GeneChip array databases and the analytical tools of Genevestigator (Hruz et al., 2008). Biclustering and hierarchical clustering

analysis of the up- and down-regulated genes in *cys-1* showed that 80% were coregulated with genes that were deregulated in wild-type seeds of the ecotype Columbia (Col-0) after treatment with 0.1% oxygen for 6 d (GSE14420; Christianson et al., 2009; Supplemental Fig. S3; Supplemental Table S2). In comparing microarray data for the gene subset categorized as biotic, 54% of the genes identified overlapped with those already shown to be affected by fungal pathogens or altered in *Pseudomonas syringae* pv *tomato* (*Pst*)-infected *Arabidopsis* plants or elicitor-treated plants (Supplemental Figs. S4 and S5; Supplemental Table S2). Among the genes identified in these groups are several transcription factors related to the biotic defense response, such as WRKY18, WRKY33, WRKY40, and the gene coding for FLG22-INDUCED RECEPTOR-LIKE KINASE1 (AT2G19190). No correlation was found with ACC treatments or mutants in ethylene signaling (Supplemental Fig. S6).

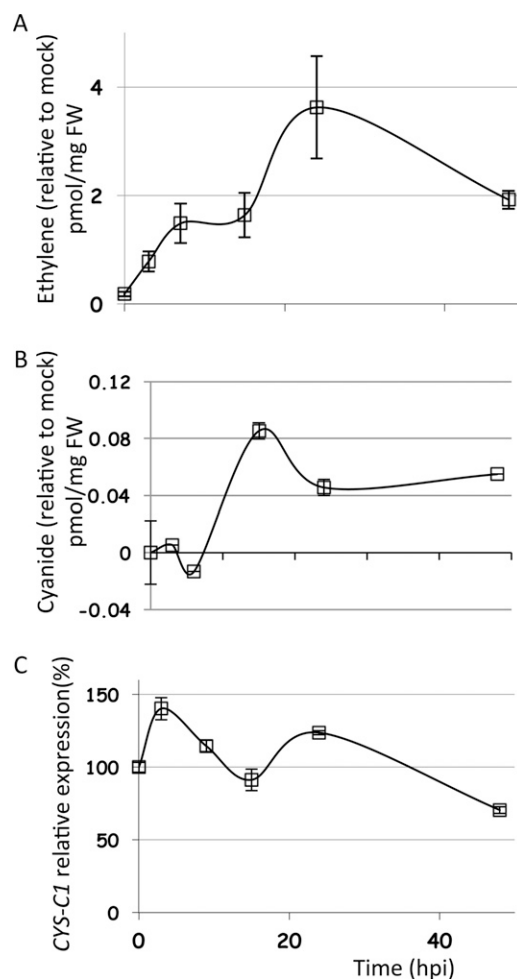

In the light of this analysis, it is interesting to speculate that cyanide plays a role in signaling and defense against pathogen infection in leaf tissues. We aimed then to investigate this hypothesis further.

#### Cyanide Accumulates during the Infection of *Arabidopsis* Plants with *Botrytis cinerea*

*B. cinerea* is a necrotrophic pathogen that causes gray mold diseases in many crop plants, resulting in significant crop losses. *B. cinerea* and other necrotrophic pathogens promote and benefit from host cell death during pathogenesis, as dead cells and necrotic tissues provide a base for saprophytic growth from which *B. cinerea* further colonizes healthy tissue (AbuQamar et al., 2006). When plants are infected by *B. cinerea*, they produce high levels of ethylene (Cristescu et al., 2002; Han et al., 2010). Figure 1A shows that the ethylene production increases rapidly in *Arabidopsis* when challenged with *B. cinerea*, reaching a maximum level at 24 h post infection (hpi). We investigated the accumulation of the cyanide coproduced during the *B. cinerea*-*Arabidopsis* interaction as well as the regulation of the *CYS-C1* gene under these conditions. At the beginning of the interaction, the level of cyanide dropped transiently at 9 hpi and then started accumulating, reaching a maximum of 190% of the basal level at 15 hpi (Fig. 1B); accordingly, *CYS-C1* expression shows a waving curve with expression peaks at 3 and 24 hpi and a valley at 15 hpi, this last level coinciding with the higher level of cyanide (Fig. 1C).

#### Cyanide Accumulation and *CYS-C1* Gene Expression Are Negatively Correlated during Compatible and Incompatible Plant-Bacteria Interactions

The bacterial pathogen *P. syringae* is a hemibiotrophic pathogen that produces bacterial specks in a wide range of plant species. In the early stages of compatible infections, host cell death does not occur. Later stages

**Figure 1.** Time course of the accumulation of ethylene and cyanide and the regulation of *CYS-C1* transcript during the *Arabidopsis*-*B. cinerea* interaction. A and B, Ethylene (A) and cyanide (B) were measured in leaf extracts of wild-type plants grown for 6 to 7 weeks and infected with a spore suspension of *B. cinerea*. The results presented are expressed as means  $\pm$  SD of a representative experiment in which 12 to 14 leaves from infected plants were pooled and three independent extractions were made from the pooled material. The experiment was repeated three times, with similar results obtained each time. FW, Fresh weight. C, The expression level of *CYS-C1* was analyzed by real-time RT-PCR and referred to the *UBQ10* internal control. The data correspond to means  $\pm$  SD of three independent analyses using material grown in different batches at different times. For each analysis, five to six plants were pooled, and three independent RNA extractions were made from the pooled material. Two experimental replicates were made for each sample. The data were normalized against the data obtained from plants treated with a mock solution. Nonnormalized data are shown in Supplemental Figures S7A, S8A, and S9A.

of infection, however, are associated with host tissue chlorosis and necrosis (Glazebrook, 2005).

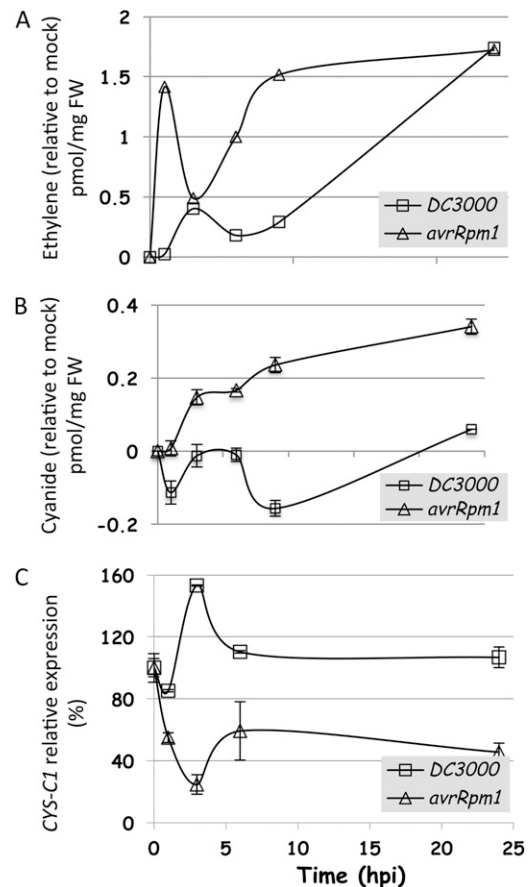

Besides the nonhost resistance, plants have the capacity to recognize pathogen-associated molecular patterns by surface pattern-recognition receptors and to induce a response leading to a basal or pathogen-associated

molecular pattern-triggered immunity (PTI; Jones and Dangl, 2006). Some pathogens have evolved to avoid recognition by delivering effectors that suppress PTI, and this results in a compatible plant-pathogen interaction. For their defense, plants have also evolved *RESISTANCE* genes that encode receptors recognizing specific pathogen effectors, resulting in effector-triggered immunity (ETI; Jones and Dangl, 2006). In addition to the PTI response, *Pst* DC3000 can elicit an ETI reaction in *Arabidopsis* when expressing the type III effector AvrRpm1 (Bent et al., 1994; Mindrinos et al., 1994; Grant et al., 1995). When tobacco plants are infected by *P. syringae*, they produce ethylene. The production is monophasic if the bacteria do not elicit a hypersensitive response (HR) and produce a disease and biphasic if the bacteria induce a HR and do not subsequently produce a disease (Mur et al., 2008). Moreover, transcriptomic data suggest that genes encoding ethylene biosynthetic enzymes were up-regulated in *Arabidopsis* following challenge with avirulent bacteria (Mur et al., 2008). To investigate this response further, the production of ethylene was monitored during compatible and incompatible interactions. *Arabidopsis* plants were infected with a virulent *Pst* DC3000 or an avirulent *Pst* DC3000 *avrRpm1* strain. Samples were taken at 1, 3, 6, 9, and 24 hpi. Ethylene was accumulated in the early stages of both interactions, although the accumulation occurred earlier in the incompatible interaction than in the compatible interaction. A second rise occurred at 9 hpi of the avirulent interaction (Fig. 2A). The infection with *Pst* DC3000 induced ethylene accumulation only at the very late stages of the interaction (24 hpi). These data are in agreement with the results already published for the tobacco-*P. syringae* interaction (Mur et al., 2008).

We also determined the kinetics of the accumulation of cyanide in the same samples. Interestingly, cyanide accumulated at different rates in the two *Arabidopsis*-*Pst* interactions, being detoxified preferentially during the compatible interaction (Fig. 2B). In fact, during ETI, cyanide started accumulating at 3 hpi, and its level did not decrease significantly during the infection. In contrast, during the PTI, cyanide content decreased at 1 hpi, increased to the basal level at 3 and 6 hpi, then decreased and started increasing again after 9 hpi, to reach the basal level of 24 hpi. Accordingly, the transcription of *CYS-C1* was induced during the compatible interaction and was repressed during the ETI, with the curve showing an opposite peak at 3 hpi (Fig. 2C).

#### Mitochondrial Cyanide Differentially Affects the Response to Necrotrophic and Biotrophic Pathogens, and This Effect Is Reversed with Hydroxocobalamin Treatment

Nonlethal concentrations of cyanide can enhance the resistance of plants to fungi (Seo et al., 2011). *cys-1* mutant plants have been shown to accumulate more cyanide in both root and leaf tissues and to exhibit less ethylene accumulation than wild-type plants (García

**Figure 2.** Time course of the accumulation of ethylene and cyanide and the regulation of *CYS-C1* transcript during the *Arabidopsis*-*P. syringae* interactions. A and B, Ethylene (A) and cyanide (B) were measured in leaf extracts of wild-type plants grown for 6 to 7 weeks and infected with a bacterial suspension of either *Pst* DC3000 or *Pst* DC3000 *avrRpm1* as described in "Materials and Methods." The results presented are expressed as means  $\pm$  SD of a representative experiment in which 12 to 14 leaves from infected plants were pooled and three independent extractions were made from the pooled material. The experiment was repeated three times, with similar results obtained each time. FW, Fresh weight. C, The expression level of *CYS-C1* was analyzed by real-time RT-PCR and referred to the *UBQ10* internal control. The data correspond to means  $\pm$  SD of three independent analyses using material grown in different batches at different times. For each analysis, five to six plants were pooled, and three independent RNA extractions were made from the pooled material. Moreover, two experimental replicates were made for each sample. The data were normalized against the data obtained from plants treated with a mock solution. Nonnormalized data are shown in Supplemental Figures S7B, S8B, and S9B.

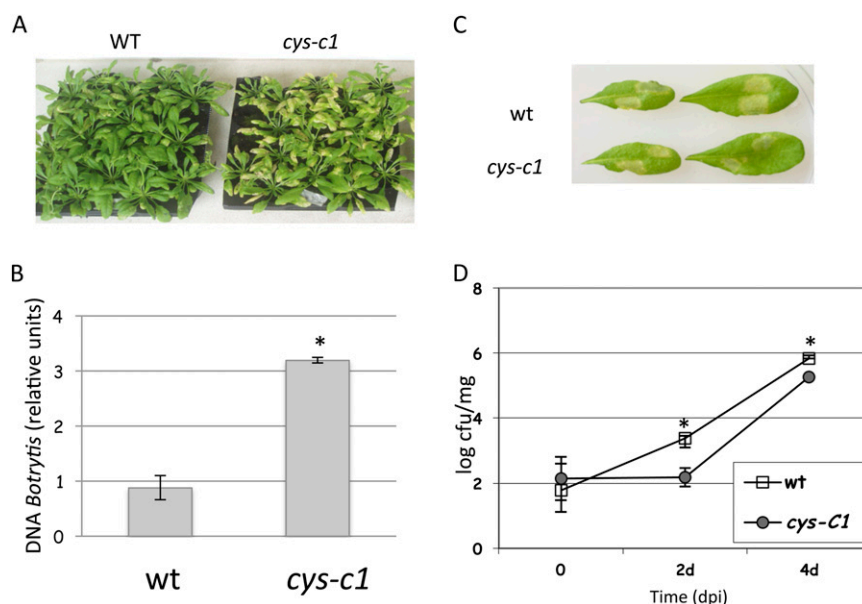

et al., 2010). To investigate the possible role of mitochondrial cyanide in plant defense against pathogens, *cys-1* mutant plants defective in the mitochondrial CAS (García et al., 2010) were challenged by a necrotrophic compatible pathogen (*B. cinerea*) and a hemibiotrophic compatible pathogen (*Pst* DC3000). When challenged with the fungus, *cys-1* showed more severe symptoms than wild-type plants and accumulated six times more

*B. cinerea* DNA (Fig. 3, A and B). Conversely, the *cys-c1* mutant exhibited a higher tolerance to the infection by *Pst* DC3000 than the Col-0 wild type, as it showed less severe symptoms than wild-type plants and accumulated 12-fold less *Pst* DC3000 colony-forming units (cfu)  $\text{mg}^{-1}$  fresh weight at 2 d post infection (dpi) than Col-0; the difference was 6-fold at 4 dpi (Fig. 3, C and D). However, the susceptibility to an avirulent strain of *Pst* DC3000 is not affected by the *cys-c1* mutation (Supplemental Fig. S10).

To confirm that the observed phenotype of the *cys-c1* mutant plants was indeed due to the disruption of the *CYS-C1* gene, complementation analysis was performed using the full-length *CYS-C1* genomic fragment including its promoter region (*Pcys-c1*). *cys-c1* plants transformed with the *Pcys-c1-CYS-C1* fragment displayed pathogen sensitivity similar to that of the wild type (Supplemental Fig. S11).

Hydroxocobalamin is a natural form of vitamin B12 that is commonly used as an antidote for severe acute cyanide poisoning in humans (Borron et al., 2007; Hall et al., 2007). Hydroxocobalamin can penetrate cells and act at an intracellular level to bind cyanide and form

nontoxic cyanocobalamin, which is excreted in the urine (Astier and Baud, 1996). In plants, hydroxocobalamin has been used to antagonize the effect of cyanide in roots, reverting the root hairless phenotype in *cys-c1* lines to that of wild-type plants (García et al., 2010). The addition of 10 mM hydroxocobalamin at the time of infection with *B. cinerea* reverted the sensitivity phenotype exhibited by the *cys-c1* mutant, decreasing the accumulation of *B. cinerea* DNA in infected *cys-c1* leaves to wild-type levels (Fig. 4A). Moreover, this effect was dose dependent, as the treatment with 5 mM hydroxocobalamin partially reverted the susceptibility of the *cys-c1* mutant to *B. cinerea* to levels similar to those of wild-type plants (Supplemental Fig. S12). Similarly, treatment with hydroxocobalamin altered the phenotype of resistance to *Pst* DC3000 exhibited by the *cys-c1* mutant, as bacteria were able to develop even better in *cys-c1* plants treated with the antidote than in wild-type plants in either the presence or absence of hydroxocobalamin (Fig. 4B). To exclude the possibility that the hydroxocobalamin directly affected pathogen growth, we performed growth tests of *Pst* DC3000 in solid culture Luria-Bertani (LB) medium in

**Figure 3.** Responses of the *cys-c1* mutant to pathogen infection. A and B, Susceptibility of the wild type (wt) and the *cys-c1* mutant to *B. cinerea* infection. A, Wild-type and *cys-c1* mutant plants after 5 d of *B. cinerea* infection. B, Quantification of fungus growth was performed by real-time PCR amplification of the *B. cinerea creA* gene, which was normalized against the Arabidopsis *UBQ10* gene. DNA was isolated from leaves 5 d after spore inoculation of 6- to 7-week-old wild-type and mutant plants grown in parallel. The data correspond to means  $\pm$  SD of at least three independent analyses made from material grown in different batches at different times. For each analysis, 20 infected plants were pooled, and six independent DNA extractions were made from the pooled material. Moreover, two experimental replicates were made from each sample. C and D, Susceptibility of the wild type and the *cys-c1* mutant to infection with virulent *Pst* DC3000 bacteria. C, Wild-type and *cys-c1* mutant leaves after 3 d of *Pst* DC3000 infection. *cys-c1* leaves show less severe symptoms than the wild type. D, The cfu were counted at 0, 2, and 4 dpi of 6- to 7-week-old wild-type and mutant plants grown in parallel. At total of 12 to 14 leaves were pooled for each analysis, in which three independent counts were made from the pooled material and two experimental replicates were made from each sample. The data correspond to means  $\pm$  SD of one representative experiment. \* $P < 0.05$ . The experiment was performed three times with material grown in different batches at different times; similar results were obtained for each iteration.

**Figure 4.** Hydroxocobalamin effect on plant susceptibility to pathogens. Wild-type (wt) and *cys-c1* mutant plants were infected with *B. cinerea* (A) or *Pst* DC3000 (B), as indicated in “Materials and Methods.” Pathogens were collected in suspensions containing (+COB) or not containing (–COB) hydroxocobalamin at the concentration indicated and used to perform the susceptibility assays. Quantification of fungus growth was performed by real-time PCR amplification of the *B. cinerea creA* gene, which was normalized against the Arabidopsis *UBQ10* gene. DNA was isolated from leaves 5 d after spore inoculation of 6- to 7-week-old wild-type and mutant plants grown in parallel. The cfu were counted at 3 dpi, with 12 to 14 leaves pooled for each analysis. Three independent determinations were made from the pooled material, and two experimental replicates were made from each sample. The data correspond to means  $\pm$  SD of one representative experiment. \* $P < 0.05$ . FW, Fresh weight.

the absence and presence of 5 mM hydroxocobalamin. No differences were observed in either of the two conditions (Supplemental Fig. S13). Therefore, the possibility of a direct effect of hydroxocobalamin in the pathogen’s growth rather than rescuing the *cys-c1* phenotype is excluded.

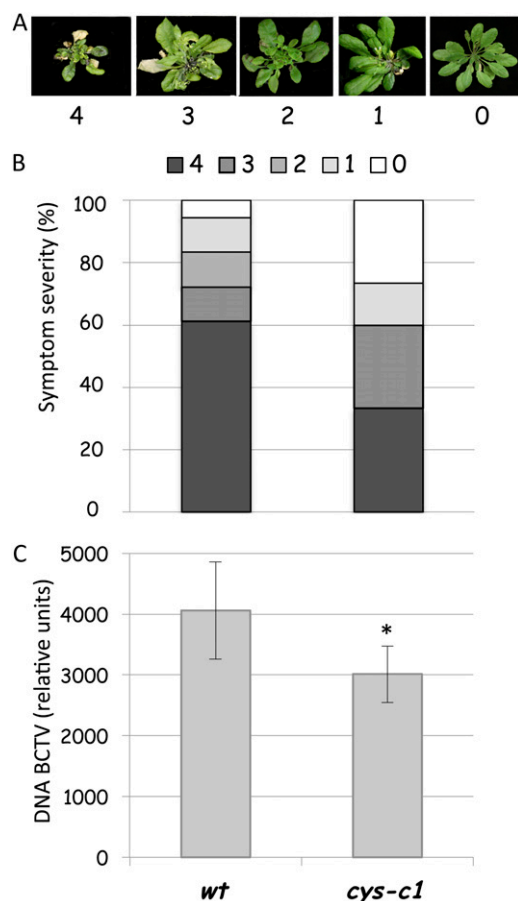

#### Mitochondrial Cyanide Is Correlated with Plant Resistance to Viral Pathogens

Nonlethal concentrations of cyanide can enhance the resistance of plants to viral infection (Chivasa and Carr, 1998; Wong et al., 2002). Members of the geminivirus

family are plant viruses with circular, single-stranded DNA genomes (Rojas et al., 2005) that infect a wide range of plant species and that cause extensive losses in crops. To determine whether mitochondrial cyanide accumulation is involved in the cyanide-related resistance to viruses, wild-type and *cys-c1* mutant plants were challenged with the geminivirus *Beet curly top virus* (BCTV). When infected with the virus, *cys-c1* plants exhibited symptoms less severe than those of respective wild-type plants (Fig. 5, A and B). Plants showing no symptoms (cataloged as 0 by the severity index described by Baliji et al. [2007]) constituted 26.6% in the case of the *cys-c1* mutant and 5.5% in the case of the wild-type plants. Moreover, the sum of plants showing the category 0 (asymptomatic) plus 1 (mild symptoms) was 40% for the *cys-c1* mutant and only 16.6% for the wild-type plants. On the other hand, 33.3% of the *cys-c1* mutant and 61.1% of the wild-type plants showed the most severe symptoms, exhibiting almost no plant growth (categorized as 4 in the severity index). When viral DNA present in infected plants was quantified by real-time PCR, the results clearly showed that the *cys-c1*-infected plants accumulated less viral DNA than did wild-type plants (Fig. 5C). These results indicate that endogenously produced cyanide can protect plants from virus attack just as exogenously applied cyanide does.

#### The *cys-c1* Mutation Produces a Reduction in Respiration Rate in Leaves and an Induction of Alternative Oxidase and *PR1* Expression

Cyanide binds to the heme iron of the mitochondrial cytochrome *c* oxidase, thereby blocking the cytochrome respiration pathway and the utilization of oxygen in cellular functions (Donato et al., 2007). In higher plants, an alternative cyanide-resistant respiratory pathway is catalyzed by the alternative oxidase (AOX), which is located in the mitochondrial inner membrane and acts as a terminal oxidase in the mitochondrial electron transport chain. AOX branches from the main respiratory chain at the level of the ubiquinone pool and catalyzes the four-electron reduction of oxygen to water, releasing the energy as heat (Millenaar and Lambers, 2003). Much work has revealed that the genes encoding AOX, AOX protein, and the alternative respiratory pathway are frequently induced during plant-pathogen interactions (Hanqing et al., 2010). The *cys-c1* mutant displays a reduction of root (García et al., 2010) and leaf (Fig. 6A) respiration rates. The addition of salicylhydroxamic acid (SHAM), an inhibitor of the AOX pathway, affects the respiration rate of wild-type and mutant plants differently, as it decreases the respiration rate of wild-type leaves only about 8% but alters the respiration rate of the *cys-c1* mutant leaves by about 24% (Fig. 6B). In both wild-type and mutant plants, the addition of potassium cyanide (KCN) reduces the oxygen uptake drastically to about 30% of the maximum respiration rate. The

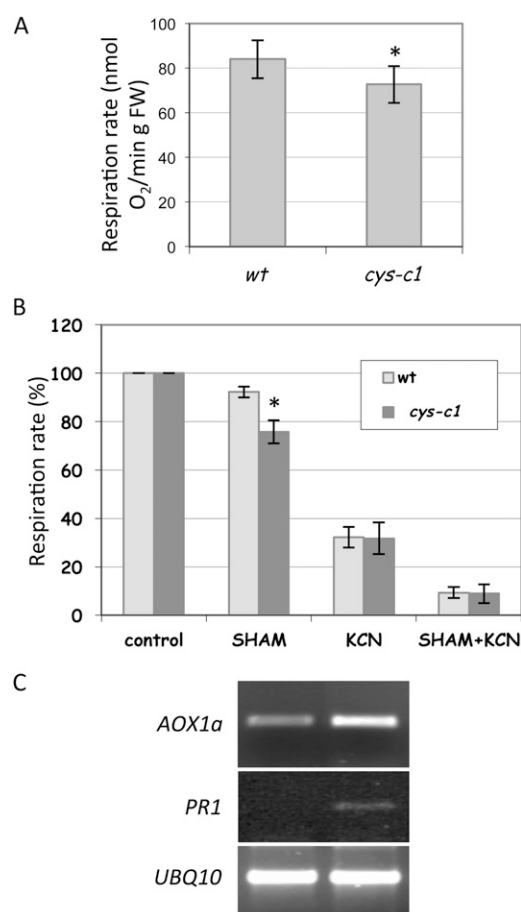

**Figure 5.** Response of the *cys-c1* mutant to virus. A, Example of the severity index described in “Materials and Methods” and Baliji et al. (2007): 0, no symptoms; 1 to 4, increasing severity of symptoms. B, Susceptibility of the wild type (wt) and the *cys-c1* mutant to BCTV infection. Whole 6- to 7-week-old plants of each genotype were agroinoculated, and the symptom severity was recorded at 28 dpi. C, Quantification of virus growth was performed in the same plants at 28 dpi by real-time PCR amplification of the viral DNA, which was normalized against the Arabidopsis *UBQ10* gene. The data correspond to means  $\pm$  SD of three independent analyses made from material grown in different batches at different times. For each analysis, at least 10 infected plants were pooled, and six independent DNA extractions were made from the pooled material. Two experimental replicates were performed from each sample. \* $P < 0.05$ . [See online article for color version of this figure.]

addition of KCN plus SHAM reduces oxygen uptake to levels lower than 10% (Fig. 6B). The increase of the AOX pathway in the *cys-c1* mutant correlates with an increase in transcript abundance of the *AOX1a* gene (Fig. 6C), which is induced by an alteration of the cytochrome respiration pathway (Albury et al., 2009; García et al., 2010). In addition, the expression of *PR1*, a pathogenesis-related protein induced by the salicylic acid-dependent pathway (An and Mou, 2011), is induced in *cys-c1* plants in the absence of stress (Fig. 6C), suggesting that endogenously produced cyanide can modulate this pathway in Arabidopsis plants.

### The *cys-c1* Mutant Accumulates Reactive Oxygen Species But Does Not Show Programmed Cell Death Lesions

One of the earliest responses to pathogen infection is the production of reactive oxygen species (ROS; Lamb and Dixon, 1997), which together with nitric oxide and salicylic acid can promote the HR (Delledonne et al., 1998; Álvarez, 2000) and lead to the activation of systemic acquired resistance, a broad-spectrum form of disease resistance (Vlot et al., 2008). Since a reduction of the respiration rate can produce an accumulation of ROS, we compared the accumulation of ROS in *cys-c1* and wild-type seedlings grown under control conditions (Fig. 7). Imaging of ROS in vivo in plant tissues by confocal laser microscopy is a very useful technique (Schneider et al., 1998). We observed a fluorescence emission resulting from the oxidation of the nonfluorescent 2',7'-dichlorodihydrofluorescein diacetate

**Figure 6.** Respiration rates (A and B) and *AOX1a* and *PR1* expression levels (C) in leaves of wild-type (wt) and *cys-c1* mutant plants. Cyanide-independent and AOX respiration were determined in the presence of 0.5 mM KCN or 4 mM SHAM, respectively. The transcription level of the AOX gene *AOX1a*, *PR1*, and the control *UBQ10* was determined by RT-PCR in leaves of noninfected 6- to 7-week-old plants. The data correspond to means  $\pm$  SD of at least three independent analyses made from material grown in different batches at different times. \* $P < 0.05$ . FW, Fresh weight.

(H<sub>2</sub>DCFDA) to a highly fluorescent product; this signal reflects significant production of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). In roots, this fluorescence was higher in *cys-c1* specimens than in wild-type samples (Fig. 7, A and B). Although chlorophyll autofluorescence interferes with the H<sub>2</sub>O<sub>2</sub> detection in green tissues, we were able to observe a higher fluorescence in *cys-c1* than in wild-type cotyledons (Fig. 7, C and D).

Because H<sub>2</sub>O<sub>2</sub> is a signaling intermediate molecule in programmed cell death, we stained the leaves of plants grown in long-day and short-day conditions with lactophenol trypan blue. We did not observe lesions characteristic of spontaneous cell death in the leaves of the *cys-c1* mutant (Fig. 7, E–H).

## DISCUSSION

Plants synthesize ethylene in response to different environmental stimuli, including pathogen attack (Wang et al., 2002; Pandey and Somssich, 2009). The role of ethylene in defense signaling in plants has been studied extensively, but its involvement remains controversial. Treatment with ethylene increases or decreases resistance to pathogens depending on the plant-pathogen interaction, and the use of mutants defective in ethylene signaling indicates a limited or different role of ethylene in the resistance to some biotrophic and necrotrophic pathogens, including fungi, bacteria, and viruses (Pieterse et al., 1998; Brading et al., 2000; Broekaert et al., 2006; Iwai et al., 2006). Cyanide is produced concomitantly with ethylene biosynthesis. In this work, however, we show different patterns of ethylene and cyanide accumulation during infection of *Arabidopsis* with both the fungus *B. cinerea* and the virulent and avirulent *P. syringae*. In addition, we show that the lack of mitochondrial CAS of *Arabidopsis*, which leads to an accumulation of

cyanide in plant tissues (García et al., 2010), results in an altered response to plant pathogens. The response is completely dependent on cyanide, as demonstrated by genetic and chemical complementation. All these data suggest that cyanide also acts in the regulation of the plant immune responses. Furthermore, the transcriptional regulation of the *CYS-C1* gene during the three plant-pathogen interactions analyzed allows a differential accumulation of cyanide in each interaction, suggesting that *CYS-C1* is involved in the signaling pathway, leading to resistance or sensitivity depending on the type of pathogen.

The classification of genes differentially expressed in *cys-c1* and wild-type plants reveals that the high endogenous cyanide content of the *cys-c1* mutant is correlated with the biotic stress response. More specifically, the cyanide accumulation is correlated with the induction of genes encoding proteins involved in the plant signaling pathway. Among the induced genes in the *cys-c1* mutant, three WRKY transcription factors, *WRKY18*, *WRKY33*, and *WRKY40*, are involved in the modulation of host defenses toward phytopathogens (Pandey and Somssich, 2009). *WRKY33* in particular was shown to be required for resistance to the necrotrophs *Alternaria brassicicola* and *B. cinerea* (Zheng et al., 2006), while *WRKY18* and *WRKY40* appear to be necessary for the resistance to *P. syringae* (Xu et al., 2006). Often, WRKY factors interact both physically and functionally in a complex pattern of overlapping or antagonistic roles. For instance, the mutation of either *WRKY18* or *WRKY40* does not affect the susceptibility of plants to either necrotrophic or biotrophic pathogens. Double *wrky18wrky40* mutants, however, are more susceptible to *P. syringae* and more resistant to *B. cinerea* than wild-type plants (Xu et al., 2006). The simultaneous activation of *WRKY18*, *WRKY33*, and *WRKY40* in the *cys-c1* mutant, then, does not necessarily lead to an additive

**Figure 7.** Accumulation of H<sub>2</sub>O<sub>2</sub> and lesion formation in the wild type (wt) and the *cys-c1* mutant. A to D, H<sub>2</sub>O<sub>2</sub> was detected by H<sub>2</sub>DCFDA staining in root (A and B) and cotyledons (C and D) from 5-d-old wild-type and *cys-c1* mutant plants cultured in MS medium. E to H, Lactophenol trypan blue was used to stain spontaneous cell death lesions. Detached leaves of plants grown in soil for 3 weeks in long-day conditions (LD; E and F) or 6 to 7 weeks in short-day conditions (SD; G and H) were used for the assay. All the experiments were repeated at least three times, with similar results obtained each time.

effect for the expression of each WRKY factor separately. In fact, we have found that cyanide accumulation correlates with an increased susceptibility to a necrotrophic pathogen, and this association would probably be due to a deleterious but nonlethal effect of cyanide itself. An intriguing increase of the tolerance to biotrophic pathogens is observed concurrently. This increased tolerance is applicable to both a bacteria and a virus and occurs together with the induction of the pathogenesis-related *PR1* mRNA in the absence of pathogens. Both susceptibility to the necrotrophic fungus and resistance to the biotrophic bacteria are reversed by treatment with the antidote hydroxocobalamin, demonstrating that the effect observed is specifically related to cyanide. Although ROS are more abundant in the *cys-c1* mutant than in wild-type plants, no PCD lesions or microlesions are observed in the mutant, which demonstrates that cyanide does not induce a lesion-mimic phenotype that could be responsible for the resistance to *Pst* DC3000 (Lorrain et al., 2003)

To discriminate between distinctive pathogens and to activate appropriate responses, plants use phytohormones for signaling. In general, responses against biotrophic pathogens include a signaling cascade dependent on salicylic acid, while necrotrophic organisms induce signaling pathways dependent on ethylene and jasmonic acid (Pieterse et al., 2009). Interactions between the different signaling pathways have been demonstrated, indicating a complex network of hormone cross talk (Koornneef and Pieterse, 2008; Spoel and Dong, 2008; Leon-Reyes et al., 2010). Exogenously applied cyanide mimics salicylic acid-induced resistance of tobacco, Arabidopsis, and tomato (*Solanum lycopersicum*) plants to viruses (Chivasa and Carr, 1998; Wong et al., 2002). More recently, this treatment has been shown to confer resistance of rice to the biotrophic fungus *Magnaporthe oryzae*, and it has been suggested that cyanide increases during the HR (Seo et al., 2011). We have demonstrated that Arabidopsis plants accumulate more cyanide when they are infected with an avirulent strain of *Pst* DC3000 than when they are challenged with the virulent strain, suggesting that this molecule has a role in the establishment of the HR. The repression of *CYS-C1* expression during the avirulent interaction and its activation during the virulent interaction further support this hypothesis. Finally, the resistance of the *cys-c1* mutant to biotrophic pathogens indicates that cyanide mimics or induces the salicylic acid signaling pathway in Arabidopsis plants.

Interestingly, *cys-c1* mutant leaves exhibit a reduced respiration rate that is more sensitive to the alternative pathway inhibitor SHAM and an enhanced expression of the *AOX1a* gene, showing that the alternative respiration pathway is activated in the mutant plants. AOX allows flexibility of plant respiratory metabolism, especially under environmental stresses (Vanlerberghe and McIntosh, 1997; Mackenzie and McIntosh, 1999), and it is induced by many adverse conditions (Hanqing et al., 2010). The induction of *AOX1a* in the *cys-c1*

mutant in nonstressed conditions could prepare it to better respond to a pathogen attack, probably by inducing a signal transduction dependent on ROS that culminates in the induction of defense proteins such as *PR1* and other proteins related to pathogenesis. It has been suggested that tobacco and tomato cyanide-induced resistance to virus is mediated by AOX, which would contribute to the signal transduction pathway leading to resistance (Chivasa and Carr, 1998; Fu et al., 2010). Strikingly, when overexpressing either the native AOX or a version of AOX mutated at its active site, tobacco mosaic virus vectors increase systemic movements in *Nicotiana benthamiana* (Murphy et al., 2004).

In summary, our results suggest that cyanide, a low- $M_r$  and highly hydrophilic molecule, acts as a signal in plants. Nitric oxide and oxygen peroxide are also low- $M_r$  molecules that are toxic at high concentrations but that exhibit a signaling role at low concentrations; their roles have been extensively demonstrated and accepted (Delledonne et al., 1998; Laloi et al., 2004). In our model, cyanide that is produced in the *cys-c1* mutant uncouples the respiratory electron chain dependent on the cytochrome *c* oxidase, and this uncoupling induces the AOX activity and the accumulation of ROS, which act by stimulating the salicylic acid-dependent signaling pathway of the plant immune system.

## MATERIALS AND METHODS

### Plant Material and Growth Conditions

Arabidopsis (*Arabidopsis thaliana*) wild-type ecotype Col-0 and the SALK\_022479 mutant were used in this work. The plants were grown in soil with a photoperiod of 8 h of white light ( $120 \mu\text{E m}^{-2} \text{s}^{-1}$ ) at 20°C/16 h of dark at 18°C. Plants were cultivated for 6 to 7 weeks. For some experiments, the plants were cultivated in solid MS medium in petri dishes supplemented with 1% Suc with a photoperiod of 16 h of white light ( $120 \mu\text{E m}^{-2} \text{s}^{-1}$ ) at 20°C/8 h of dark at 18°C.

To generate the *cys-c1* complementation line (*cys-c1::Pcys-c1-CYS-C1*), a 2,949-bp genomic fragment containing the full-length coding sequence of *CYS-C1* plus the intergenic region between *CYS-C1* and its contiguous *PIP1* gene (At3g61430) was obtained by PCR amplification using the proofreading Platinum Pfx DNA polymerase (Invitrogen) and the primers C1GW-F and C1GW-R (Supplemental Table S3). The fragment was cloned into the pENTR/D-TOPO vector (Invitrogen) and transferred into the pMDC99 vector (Curtis and Grossniklaus, 2003) using the Gateway system (Invitrogen) according to the manufacturer's instructions. The final construct, *Pcys-c1-CYS-C1*, was generated by transformation into *Agrobacterium tumefaciens* and then introduced into *cys-c1* null plants using the floral dip method (Clough and Bent, 1998).

### Respiration Measurements in Leaves

Wild-type and mutant plants were grown for 6 to 7 weeks in soil. Approximately 50 mg of leaf tissues was cut and transferred into air-tight cuvettes containing 20 mM HEPES (pH 7.2) and  $\text{CaCl}_2$ , and oxygen uptake was measured as a decrease of oxygen concentration in the dark using a Clark-type electrode. Cyanide-resistant oxygen uptake was measured in the presence of 0.5 mM KCN. The component of the change due to the AOX pathway was determined by measurement in the presence of 4 mM of the inhibitor SHAM.

### Bacterial Pathogen Infections

The bacterial strains used in this study were *Pseudomonas syringae* pv *tomato* DC3000 and *Pst* DC3000 bearing a plasmid containing the *avrRpm1* avirulence gene (Grant et al., 1995). For treatment of the plants, bacterial cultures were

collected from plates in 10 mM MgCl<sub>2</sub>, and their concentrations were adjusted to  $5 \times 10^6$  bacteria mL<sup>-1</sup> (optical density at 600 nm = 0.01; *Pst* DC3000 *avrRpm1*) or  $2.5 \times 10^6$  bacteria mL<sup>-1</sup> (optical density at 600 nm = 0.005; *Pst* DC3000). Sterile 10 mM MgCl<sub>2</sub> was used as a mock solution. The bacterial suspension or the mock solution was then pressure infiltrated into the abaxial side of the leaves of 6- to 7-week-old plants using a syringe without a needle. Wild-type, mutant, and complemented plants were grown at the same time using the same conditions (Swanson et al., 1988).

## Bacteria and Growth Tests

*Pst* DC3000 *avrRpm1* bacteria were collected from LB plates supplemented with rifampicin (50 µg mL<sup>-1</sup>) in 10 mM MgCl<sub>2</sub>, and their concentration was adjusted to  $5 \times 10^6$  bacteria mL<sup>-1</sup> (optical density at 600 nm = 0.01). To determine whether hydroxocobalamin affects bacterial viability, growth tests were performed as described previously (Álvarez et al., 2012a) by supplementing the growth medium with 5 mM hydroxocobalamin instead of 0.5 mM Cys. Six series of 1:10 dilutions were performed. In all, 10 µL of the resulting suspensions was plated, grown for 48 h at 28°C, and subsequently photographed (Supplemental Fig. S13).

## In Planta Growth of Virulent or Avirulent *Pst* DC3000

The protocol for measuring the growth of bacteria was adapted from (Tornero and Dangl, 2001). Wild-type, mutant, and complemented plants were grown for 6 to 7 weeks at the same time and in the same conditions and inoculated with bacterial pathogens as described above. One hour after the inoculation, the samples for day 0 were taken. To determine bacterial growth, 100 mg of leaves was ground in 500 µL of 10 mM MgCl<sub>2</sub> and gently vortexed. In all, 20 µL from each sample was added to the wells of a microtiter plate containing 180 µL of 10 mM MgCl<sub>2</sub>, and serial 10-fold dilutions were plated on petri dishes containing 50 mg mL<sup>-1</sup> rifampicin. The plates were incubated at 30°C, and the number of colonies was counted 30 h later. The number of cfu mg<sup>-1</sup> fresh weight was determined by the formula  $\text{cfu mg}^{-1} \text{ fresh weight} = k(N \times 10^{d-1}) / (\text{weight of the tissue})$ , where  $N$  is the number of colonies counted in the dilution number  $d$  and the constant  $k$  (500 in our case) represents the number of cfu present in the sample per colony appearing in the first dilution (Tornero and Dangl, 2001).

## Fungal Infections

The *Botrytis cinerea* strain ME4 was grown in a solid strawberry broth for 12 d, and spore suspensions were prepared at a concentration of  $5 \times 10^5$  spores mL<sup>-1</sup> in 12 g L<sup>-1</sup> potato dextrose broth. Six- to 7-week-old wild-type, mutant, and complemented plants grown at the same time and in the same conditions were pulverized with a Preval sprayer with spore suspension. Approximately 2 mL of spore suspension per plant was used. The plants were covered with a transparent film to maintain 100% humidity. The samples were collected for PCR analysis after 5 d.

## Quantification of *B. cinerea* DNA Accumulation in Infected Plants

DNA from infected plants was quantified by real-time PCR according to a previous study (Calo et al., 2006). DNA from the *B. cinerea* *creA* gene (Tudzynski et al., 2000) was amplified using the oligonucleotides *creABOT-F* and *creABOT-R* (Supplemental Table S3). As an internal standard to normalize the real-time PCR *Arabidopsis UBQ10* DNA was amplified using the oligonucleotides *qUBQ10F* and *qUBQ10R* (Supplemental Table S3). Relative quantifications were performed by subtracting the cycle threshold (CT) value of *UBQ10* from the CT value of *creA* ( $\Delta\text{CT}$ ). The relative *B. cinerea* DNA was calculated as  $2^{-\Delta\text{CT}}$ .

## Geminivirus Infection Assays

Infection of *Arabidopsis* plants with *Beet curly top virus* was performed by whole plant agroinoculation as described (Briddon et al., 1989; Lozano-Durán et al., 2011). Inoculated plants were scored for the appearance of symptoms typical of a BCTV infection on systemically infected tissue. Symptom severity was evaluated at 28 dpi according to the severity index described by Baliji

et al. (2007), where 0 represents symptomless plants and 1 to 4 represent plants showing increasing symptom severity. The infection assay was performed in triplicate.

## Quantification of BCTV DNA Accumulation in Infected Plants

Total DNA of infected plants was extracted at 28 dpi using the DNeasy Plant Mini Kit (Qiagen) and digested with *DpnI* to differentiate between viral DNA originating from a replication in planta, which is not methylated, and viral DNA originating from replication in the inoculum of *A. tumefaciens*, which is methylated. Viral DNA accumulation was quantified by real-time PCR using the primers BCTV-F and BCTV-R (Supplemental Table S2). As an internal standard to normalize the real-time PCR, *Arabidopsis UBQ10* DNA was amplified using the oligonucleotides *qUBQ10F* and *qUBQ10R* (Supplemental Table S3). Relative quantifications were performed by subtracting the CT value of *UBQ10* from the CT value of *BCTV* ( $\Delta\text{CT}$ ). The relative BCTV DNA was calculated as  $2^{-\Delta\text{CT}}$ .

## H<sub>2</sub>O<sub>2</sub> Detection

For the fluorimetric detection of H<sub>2</sub>O<sub>2</sub>, 5-d-old seedlings were incubated with 10 µM H<sub>2</sub>DCFDA (Molecular Probes) for 5 min in the presence of 10 µM propidium iodide (López-Martín et al., 2008). Samples were observed using a Leica TCS SP2 spectral confocal microscope with excitation of 488 nm and an emission range of 500 to 550 nm for fluorescein detection and 600 to 650 nm for propidium iodide detection.

## Cell Death Staining

Trypan blue staining for dead cells in leaves was performed as described previously (Carol and Dolan, 2006) by incubating the leaves in a lactic acid-phenol-trypan blue solution (2.5 mg mL<sup>-1</sup> trypan blue, 25% [w/v] lactic acid, 23% phenol, and 25% glycerol), heating them over boiling water for 1 min, and finally destaining them using a 2.5 g mL<sup>-1</sup> chloral hydrate solution before photographing the leaves.

## Ethylene Determination by Gas Chromatography

A total of 100 to 300 mg of infected leaves was collected, weighted, placed inside a 12-mL vial, and finally sealed. The amount of ethylene produced and released to the gas phase during 24 h was determined by gas chromatography by injecting 1 mL of the head space onto a GC2010 apparatus equipped with an activated alumina column and a flame ionization detector. The oven and the detector temperatures were isothermally maintained at 80°C and 150°C, respectively. The results are expressed as means  $\pm$  SD from at least five replicate samples, and the experiment was repeated three times from independent samples.

## Cyanide Determination by HPLC

A total of 100 mg of plant tissue was homogenized using a mortar and pestle with liquid nitrogen and resuspended in cold borate-phosphate extraction buffer (2 mL g<sup>-1</sup> fresh weight) containing 27 mM sodium borate and 47 mM potassium phosphate, pH 8.0. Homogenates were centrifuged at 15,000g for 15 min at 4°C. Extracted cyanide was subsequently quantified by reverse-phase HPLC after derivatization with 2,3-naphthalenedialdehyde to form a 1-cyano-2-alkyl-benz[*f*]isoindole derivative by previously described methods (Lin et al., 2005; García et al., 2010).

## RNA Isolation and Semiquantitative RT-PCR

Total RNA was extracted from *Arabidopsis* leaves using the RNeasy Plant Mini Kit (Qiagen) and reverse transcribed using an oligo(dT) primer and the SuperScript First-Strand Synthesis System for RT-PCR (Invitrogen) following the manufacturer's instructions. *AOX1a* and *PR1* expression was determined by semiquantitative PCR using an aliquot of the complementary DNA (cDNA) and the oligonucleotides shown in Supplemental Table S3. The constitutively expressed *UBQ10* gene was used as a control. The PCR conditions were as follows: a denaturation cycle of 2 min at 94°C; 30 amplification cycles of 1 min

at 94°C, 1 min at 60°C, and 1 min at 72°C; and an extension cycle of 5 min at 72°C.

### Real-Time RT-PCR

Quantitative real-time RT-PCR was used to validate microarray data and to analyze the expression of the *CYS-C1* gene. First-strand cDNA was synthesized as described above. Gene-specific primers for each gene were designed using the Vector NTI Advance 10 software (Invitrogen; Supplemental Table S3). Real-time PCR was performed using iQ SYBR Green Supermix (Bio-Rad), and the signals were detected on an iCYCLER (Bio-Rad) according to the manufacturer's instructions. The cycling profile consisted of 95°C for 10 min followed by 45 cycles of 95°C for 15 s and 60°C for 1 min. A melt curve from 60°C to 90°C was run following the PCR cycling. The expression level of each gene was normalized to that of the constitutive *UBQ10* gene by subtracting the CT value of *UBQ10* from the CT value of the gene ( $\Delta$ CT). The fold change was calculated as  $2^{-(\Delta$ CT mutant -  $\Delta$ CT wild type).

### RNA Extraction and Microarray Hybridization

For microarray studies of the *cys-c1* mutant, plants were grown on MS plates supplemented with 1% Suc under a photoperiod of 16 h of white light ( $120 \mu\text{E m}^{-2} \text{s}^{-1}$ ) at 20°C/8 h of dark at 18°C. Leaves of 15-d-old plants were used for total RNA isolation with TRIzol reagent (Invitrogen) and cleaning with the RNeasy Plant Mini Kit (Qiagen). The resulting material was used to synthesize biotinylated complementary RNA (cRNA) for hybridization to Arabidopsis ATH1 arrays (Affymetrix) using the 3' Amplification One-Cycle Target Labeling Kit. Briefly, 4 mg of RNA was reverse transcribed to produce first-strand cDNA using a (dT)<sub>24</sub> primer with a T7 RNA polymerase promoter site added to the 3' end. After second-strand synthesis, in vitro transcription was performed using T7 RNA polymerase and biotinylated nucleotides to produce biotin-labeled cRNA. The cRNA preparations (15  $\mu\text{g}$ ) were fragmented into fragments of 35 to 200 bp at 95°C for 35 min. These fragmented cRNAs were hybridized to the Arabidopsis ATH1 microarrays at 45°C for 16 h. Each microarray was washed and stained in the Affymetrix Fluidics Station 400 following standard protocols. Microarrays were scanned using the Affymetrix GeneChip Scanner 3000.

### Microarray Data Analysis

Microarray analysis was performed using the affyImGUI R package (Wettenhall et al., 2006). The Robust Multiarray Analysis algorithm was used for background correction, normalization, and summarizing expression levels (Irizarry et al., 2003). Differential expression analysis was performed using Bayes *t* statistics and the linear models for microarray data (Limma), which are included in the affyImGUI package. *P* values were corrected for multiple testing using the false discovery rate method (Benjamini and Hochberg, 1995; Reiner et al., 2003). Cutoff values of 2-fold change and  $P < 0.05$  were adopted to discriminate the expression of genes that were differentially expressed in the mutant plant with respect to the wild type. Gene classification into functional groups was determined using the Bio-Array Resource for Arabidopsis Functional Genomics (Toufighi et al., 2005) and MapMan software (<http://gabi.rzpd.de/projects/MapMan/>). The microarray data for the *cys-c1* mutant were meta-analyzed using Genevestigator (Hruz et al., 2008).

### Statistical Analysis

For all the experiments shown, at least three independent samples were analyzed (for details, see the figure legends). An ANOVA statistical analysis of data was performed using the program OriginPro 7.5 (OriginLab).

Sequence data from this article can be found in the GenBank/EMBL data libraries under accession numbers CYS-C1 (At3g61440) and CYS-C1 T-DNA mutant (SALK\_022479). The microarray Gene Expression Omnibus accession number is GSE19242.

### Supplemental Data

The following materials are available in the online version of this article.

**Supplemental Figure S1.** Analysis of the *cys-c1* transcriptome.

**Supplemental Figure S2.** Relative expression levels of selected genes in the *cys-c1* mutant plants.

**Supplemental Figure S3.** Graphic display of the hierarchical clustering of *cys-c1* up- or down-regulated genes in response to hypoxia, performed with Genevestigator (Hruz et al., 2008).

**Supplemental Figure S4.** Graphic display of the meta-profile analysis of *cys-c1* up- or down-regulated genes in response to biotic stresses, performed with Genevestigator (Hruz et al., 2008).

**Supplemental Figure S5.** Graphic display of the hierarchical clustering of *cys-c1* up- or down-regulated genes in response to elicitors and pathogens, performed with Genevestigator (Hruz et al., 2008).

**Supplemental Figure S6.** Graphic display of the hierarchical clustering of *cys-c1* up- or down-regulated genes in response to ACC treatment and in the *etr1-1* mutant, performed with Genevestigator (Hruz et al., 2008).

**Supplemental Figure S7.** Time course of the accumulation of ethylene during the Arabidopsis-*B. cinerea* interaction (A) and the Arabidopsis-*P. syringae* interactions (B).

**Supplemental Figure S8.** Time course of the accumulation of cyanide during the Arabidopsis-*B. cinerea* interaction (A) and the Arabidopsis-*P. syringae* interactions (B).

**Supplemental Figure S9.** Time course of the expression of *CYS-C1* during the Arabidopsis-*B. cinerea* interaction (A) and the Arabidopsis-*P. syringae* interactions (B).

**Supplemental Figure S10.** Susceptibility of the wild type and the *cys-c1* mutant to infection with avirulent *Pst* DC3000 *avrRpm1* bacteria.

**Supplemental Figure S11.** Genetic complementation of the pathogen-associated phenotype of the *cys-c1* mutant.

**Supplemental Figure S12.** Dose-dependent effect of hydroxocobalamin on plant susceptibility to *B. cinerea*.

**Supplemental Figure S13.** Growth tests of *Pst* DC3000 bacteria grown in LB medium supplemented with rifampicin and 5 mM hydroxocobalamin (COB 5 mM) or with rifampicin alone (–COB).

**Supplemental Table S1.** List of differentially regulated genes in leaves of the *cys-c1* mutant compared with the wild type.

**Supplemental Table S2.** Pathogen- and hypoxia-regulated genes in the *cys-c1* mutant.

**Supplemental Table S3.** Oligonucleotide sequences used in this work.

### ACKNOWLEDGMENTS

We acknowledge Dr. Olga Del Pozo for providing the bacterial strains used in this work.

Received April 10, 2013; accepted June 19, 2013; published June 19, 2013.
