Abstract

The cellular response to 100 ns pulsed electric fields (nsPEF) exposure includes the formation of transient nanopores in the plasma membrane and organelle membranes, an immediate increase in intracellular Ca²⁺, an increase in reactive oxygen species (ROS), DNA fragmentation and caspase activation. 100 ns, 30 kV/cm nsPEF stimulates an increase in ROS proportional to the pulse number. This increase is inhibited by the anti-oxidant, Trolox, as well as the presence of Ca²⁺ chelators in the intracellular and extracellular media. This suggests that the nsPEF-triggered Ca²⁺ increase is required for ROS generation.

Keywords

apoptosis; ablation; nanosecond pulses; ROS; nanoelectroablation

Introduction

Ultrashort, high voltage electric pulses in the nanosecond domain have been found to generate transient pores 1 nm in diameter in both the plasma membrane [6;13;19] and intracellular organelle membranes [1; 26] with a lifetime of several minutes. These nanopores lead to a rapid increase in intracellular Ca²⁺ ([Ca²⁺]_i) from extracellular Ca²⁺ influx as well as Ca²⁺ release from the endoplasmic reticulum. In addition, water influx leads to swelling and bleb formation [21]. Downstream changes observed following nanosecond pulsed electric field (nsPEF) application include most of the events normally referred to as apoptosis, including reactive oxygen species (ROS) generation [20], caspase activation [4;8;22] and DNA fragmentation [14;27]. These observations have led to the use of nsPEF in cancer therapy to ablate tumors [2;7;11;14-18] which we have called “nanoelectroablation”.

We are very interested in the signal transduction pathway involved in nanoelectroablation. What are the critical steps leading to apoptosis following nsPEF exposure? The [Ca²⁺]_i increase is probably a key step since this Ca²⁺ change is observed immediately after the pulse and a change in intracellular Ca²⁺ is known to influence so many cellular processes.

We want to determine if the $[Ca^{2+}]_i$ increase is required for any of the other downstream changes observed following nsPEF exposure. ROS generation begins within a minute after nsPEF exposure and continuously increases for over an hour [20]. This could be important for subsequent cellular changes since ROS is known to trigger DNA damage [29] and mitochondrial membrane permeabilization [10]. Here we present studies using both intracellular and extracellular Ca^{2+} chelators that suggest that the nsPEF-triggered increase in $[Ca^{2+}]_i$ is required for ROS generation.

Materials and Methods

Cell lines

BxPC-3 cells were purchased from ATCC (Manassas, Virginia). Cells were maintained in exponential growth in RPMI-1640 medium supplemented with 10% fetal bovine serum and 5% penicillin-streptomycin. They were maintained in 37°C/5% CO₂ incubator.

Detecting Reactive Oxygen Species

Reactive oxygen species generation was detected by using Image-iT™ LIVE Green Reactive Oxygen Species Detection Kit which was purchased from Invitrogen (Carlsbad, CA). Carboxy-H₂DCFDA (carboxy-2',7'-dichlorofluorescein diacetate), a fluorogenic marker, is cell-permeant and is trapped inside the cell when it is deacetylated by cellular esterases. The reduced form, carboxy-DCFH, is oxidized by any presence of ROS to form carboxy-DCF which is fluorescent. Some minor changes were made to the manufacturer's protocol for optimal imaging. The cells were labeled with carboxy-H₂DCFDA (25 μM) in HBSS/Ca²⁺/Mg²⁺ at 37°C in the dark for 1 hour. After being washed twice, the cells were resuspended in HBSS/Ca²⁺/Mg²⁺ and were ready for nsPEF treatment. For a positive control, cells incubated with either 1 mM H₂O₂ or 10 mM ethanol in HBSS/Ca²⁺/Mg²⁺ for 1 hour in dark at 37 °C prior to labeling with fluorescent dye were also exposed to the same electric field.

Inhibition effect of antioxidant

In order to demonstrate that we were measuring reactive oxygen species, we compared our signals with cells that were pretreated with 1 mM Trolox C (6-hydroxy-2,2,5,7,8-pentamethylchroman) (EMD Millipore, Billerica, MA) for 1 hour at 37 °C followed by a wash. This antioxidant prevents oxidation by scavenging free radicals.

Ca²⁺-dependence of ROS

In order to observe the Ca²⁺-dependence of ROS production, two chelators were used. BAPTA-AM (Invitrogen, Carlsbad, CA) was used to chelate intracellular Ca²⁺ (Ca²⁺_i), while EGTA (Invitrogen, Carlsbad, CA) was used to chelate any extracellular Ca²⁺ (Ca²⁺_o). Four conditions were tested: 1) Normal Ca²⁺ inside and out, 2) EGTA added to chelate Ca²⁺_o; 3) BAPTA-AM pretreatment to chelate Ca²⁺_i; 4) Both EGTA outside and pre-loading with BAPTA-AM to chelate Ca²⁺_i. One μM BAPTA-AM and 1X PowerLoad (Invitrogen) were added along with 25 μM carboxy-H₂DCFDA in HBSS/ Ca²⁺/Mg²⁺ for 1 hour in the dark at room temperature before washing and resuspending. Ca²⁺_o was chelated after ROS dye incubation and washing by adding 5 mM Na-EGTA (pH 7.4) 5 minute before nsPEF stimulation.

Slide Chamber

Two pieces of 3 mm × 6 mm platinum foil (25 μm thick) were cut and their edges polished with polishing paper. The platinum foil pieces were attached to the coverslip with paraffin with their polished edges facing each other. The slide was removed from the hot plate after

the gap between the two pieces was adjusted to the desired width by positioning the platinum pieces under the microscope. Excess paraffin within the channel of the metal electrodes was removed with acetone. Three μl of cells at a concentration of 105 cells/ml were loaded into the 100 μm -wide gap between two sheets of platinum foil on the coverslip glass chamber. A glass coverslip (round, 12 mm) was placed over the gap to reduce evaporation.

NsPEF Pulse Generator

The pulse generator used is capable of generating 100 ns pulses up to 1 kV in amplitude. It does this by charging and then rapidly discharging a pulse forming network (PFN) in the Blumlein configuration. This PFN was built using a small coaxial cable (RG-174/U) as a transmission line. The length of the cable used to generate the 100 ns pulse was 65 ft. This cable was loosely wound into a coil approximately 6" in diameter so that it could be easily enclosed in a portable, shielded box. The high voltage power supply charging this PFN is an EMCO G10 (Sutter Creek, CA). This power supply charges the PFN through a large 10M resistor placed in series with the PFN at the power supply output. To adjust the HV power supply control voltage, we use a digital potentiometer (AD7376). In order to rapidly discharge the PFN (generating the pulse), a 1kV RF N-Channel MOSFET (DE275-102N06A) was driven by an RF FET driver (DEIC420). When this FET discharges the voltage on the PFN, the 100 ns pulse is generated and delivered to the load (fig. 1A) with an impedance-matching resistor placed in parallel with the load.

Spring-loaded gold contacts press onto the metal pads for electrical contact to the output cabling from the pulse generator (fig. 1B). By placing a current sensor on one of the wires to the load, the current delivered to the load was also recorded (fig. 1A). This system was isolated and powered by a 16.8 V, 2300 mAh NiMH rechargeable battery to prevent applying noise onto the mains power. All communication to the system was done via fiber optic from a user control box. The user may adjust the output (charging) voltage, the pulse frequency and the number of pulses to be delivered. For all experiments mentioned, 100 ns, 30 kV/cm pulses were delivered at a frequency of 5 pps to BxPC-3 cells.

Data acquisition

The carboxy- H_2DCFDA fluorescence is optimally excited at 492 nm. To observe the fluorescence changes in the cells, digital images were taken before, during, and after the cells have received nsPEF treatment. The slide chamber holding the cells was placed on a microscope (Olympus IX71 inverted using 100X 1.30 NA objective). A cooled CCD camera (Pixera Penguin Model 600CL, Santa Clara, CA) with 24 bit resolution was mounted onto the microscope. LabVIEW (National Instruments, Austin, TX) was used to control the excitation light shutter (VCM-D1, Vincent Associates, Rochester, NY) to open at pre-determined rates (1 sec every minute, 5 sec every minute, 5 sec every 15 sec), as well as image acquisition. Fluorescence images were taken with the camera in fixed gain mode using a $\frac{1}{2}$ second exposure to avoid any auto-adjustment of the gain. In order to avoid this photo-activation of the dye artifact, we limited the fluorescent light exposure to 1 s for each time point and only collected one time point per minute.

Photon counting was accomplished with a photomultiplier (PMT-100, Applied Scientific Instrumentation, Eugene OR). The photomultiplier was mounted on the camera port of the inverted fluorescence microscope (Model IX71, Olympus Corp., Center Valley, PA) with a beam splitter that directed infrared to a video camera to enable selection of the region of interest (ROI) and ROS fluorescence from the ROI to the photomultiplier for photon counting. The fluorescence light shutter was opened for a fixed amount of time under LabVIEW control (National Instruments, Austin, TX) and the photomultiplier generated a

voltage signal proportional to the photons emitted. The photomultiplier gain used was 6-7 for optimal signal with minimal overexposure and the data were logged using a program written in LabVIEW.

Statistical analysis

Each experiment was repeated at least three times. Data collected on the Olympus microscope was analyzed with the use of Image J and plotted in graphs as level of gray. Voltage data acquired from the photomultiplier were converted to photons/s using calibrations curves supplied with the photomultiplier.

Results

Since the ROS-sensitive dye, carboxy-H₂DCF, is known to be photoactivated [20], we limited the exposure time to excitation light to either 1 or 5 s per min. We also performed both positive controls with H₂O₂ and negative controls with the antioxidant, Trolox C (a water soluble vitamin E analog) (fig. 2). The positive control gave a very strong ROS signal, and when cells were pre-incubated with 1 mM Trolox C for 1 hour, reactive oxygen species production was strongly inhibited ($P < 0.001$), supporting our conclusion that this signal represents ROS.

The application of 30 kV/cm, 100 ns pulses at 5 pps to BxPC-3 cells caused the oxidation of H₂DCF, presumably from ROS production (fig. 2). ROS levels in nsPEF- exposed cells progressively increased over time (Fig. 2, 3) and were proportional to the number of nsPEF pulses applied (Table 1)

We also measured the level of carboxy-H₂DCF fluorescence with the more sensitive photomultiplier tube. The resting ROS signal in unstimulated cells ($3.6 \pm 0.2 \times 10^7$ photons/s) was reduced 2.5-fold by pretreatment with 1 mM Trolox C ($1.4 \pm 0.1 \times 10^7$ photons/s). After stimulating with 100 pulses, the number of photons from a single BxPC-3 cell, pretreated with 1 mM Trolox C doubled to $2.7 \pm 0.2 \times 10^7$ photons/s, while the number of photons from untreated cells increased nearly 3-fold to $10.4 \pm 1.1 \times 10^7$ with a p value < 0.001 . By 6 minutes after nsPEF exposure, the mean number of photons/s was $4.2 \pm 0.2 \times 10^7$ and $13.6 \pm 1.4 \times 10^7$ photons/s in unstimulated and stimulated cells, respectively, with p-value < 0.001 .

A similar result was observed with fluorescence imaging (figure 3). The mean fluorescence intensity increased most steeply in nsPEF-treated cells and those pretreated with 1 mM Trolox C began exhibited a much weaker response. 10 μ M Trolox C had no significant effect on ROS formation.

Ca²⁺-Dependence of ROS

Next, we investigated the role of Ca²⁺ in the production of ROS by chelating intracellular and extracellular Ca²⁺. ROS stimulation was greatest under normal Ca²⁺ conditions. When BAPTA-AM was used to chelate intracellular Ca²⁺, ROS production was reduced by a factor of two. However, since extracellular Ca²⁺ can enter through the nanopores induced in the plasma membrane by the pulses we would expect it to exceed the buffering capacity of the internal BAPTA. The only way to prevent this is to buffer extracellular Ca²⁺ as well. When EGTA is used to chelate extracellular Ca²⁺ alone, ROS production is even lower than that when Ca²⁺_i was chelated. However, when both intracellular and extracellular Ca²⁺ were chelated the ROS level dramatically dropped to 90-94% of control levels (fig. 4). These results suggest that Ca²⁺ plays an important role in the nsPEF-triggered increase in ROS in BxPC-3 cells.

Discussion

New Findings

We show here that ROS generation is triggered by nsPEF treatment in human pancreatic cancer cells. We have used conditions that minimize photoactivation of the ROS-sensing fluorescent dye as indicated by the insignificant increase in ROS in cells imaged without pulsing (fig. 3). The inhibition of the fluorescent signal by the antioxidant, Trolox, provides further evidence that this signal represents ROS. Most significantly, we find that this ROS increase can be greatly inhibited by preventing the normal nsPEF-induced increase in intracellular Ca^{2+} . Since the increase in ROS is required for normal apoptosis [25], this Ca^{2+} -dependence suggests that the nsPEF-induced Ca^{2+} increase is required for apoptosis and is one of the earliest steps in the apoptotic pathway.

Previous Work

Pakhomova, et al. [20] were the first to report ROS generation by nsPEF exposure to cells in culture. They also found that the amount of ROS generated increased with increasing pulse number and continued to increase for over an hour after nsPEF exposure. Two earlier reports that failed to detect ROS generation following 10 pulses 300 ns long used a flow cytometer. Perhaps the ROS-sensitive dye leaked out of those cells during the transfer [8;22].

ROS generation was also detected following the much longer, microsecond pulsed field application as well and this also appears to depend on an increase in intracellular Ca^{2+} [5;9;24]. However this microsecond pulsed field response does not usually result in apoptosis. Therefore, the ROS increase alone is probably insufficient to trigger apoptosis. Since one difference between the microsecond pulses and nanosecond pulses is the ability of the latter to penetrate into the cytoplasm, some other cytoplasmic target may also be required. Recently Beebe's group reported that the nsPEF-triggered mitochondrial depolarization is the best predictor of cell death [3;23]. This involvement of mitochondria in apoptosis was also proposed by Weaver [28] who suggested that overloading mitochondria with Ca^{2+} via multiple pulses would lead to swelling and bursting to release cytochrome C and trigger caspase activation.

Targets of ROS

There are at least three known targets of ROS in apoptosis: 1) ROS is known to cause chromatin dysfunction such as single and double strand DNA fragmentation [12;29]. 2) Recently Bid-induced mitochondrial membrane permeabilization was shown to occur in waves propagated by ROS signaling [10]; 3) FAS-mediated apoptosome formation is dependent on ROS [25]. There is much work to be done to determine which if any of these possible targets are affected by the nsPEF-induced ROS increase.

Acknowledgments

We thank Andrei Pakhomov for his advice on the photo-activation of Carboxy- H_2DCFDA . This work was supported by NIH Grants R01CA125722 and R44CA150484 to RN.

Highlights

100 ns, 30 kV/cm electric pulses stimulate an increase in reactive oxygen species (ROS) in human pancreatic carcinoma cells.

This ROS increase is proportional to the number of pulses applied.

This ROS increase is inhibited by blocking the increase in intracellular Ca^{2+} and by the presence of the anti-oxidant, Trolox.

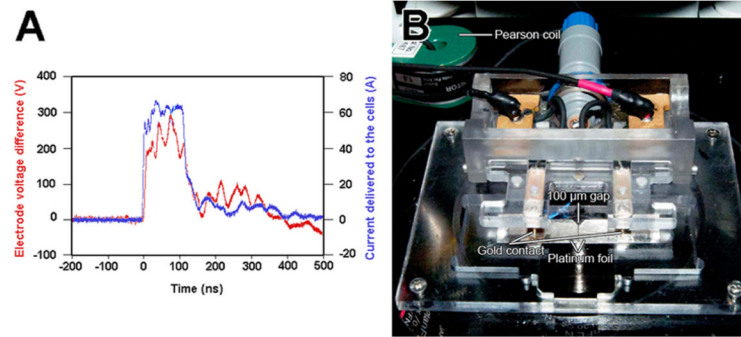

Figure 1. Microscope stage-mounted slide holder with contact electrodes and waveform. A. Oscilloscope trace of the 100 ns long voltage (red) and current (blue) pulse applied to the cells using the chamber on the right. B. Chamber that mounts on the microscope stage to apply the pulse to the cells in the 100 μm -wide gap between two pieces of Pt foil.

Figure 2. Superimposed DIC and Fluorescence images of BxPC-3 cells that have been loaded with Carboxy-H₂DCFDA and exposed to the indicated number of 100 ns pulses at 30 kV/cm at 5 pps. Images were taken at the minutes after nsPEF exposure indicated by the numbers in the top row. Fluorescence excitation was limited to a 5 s exposure once per minute and each fluorescence image was acquired in 0.5 s.

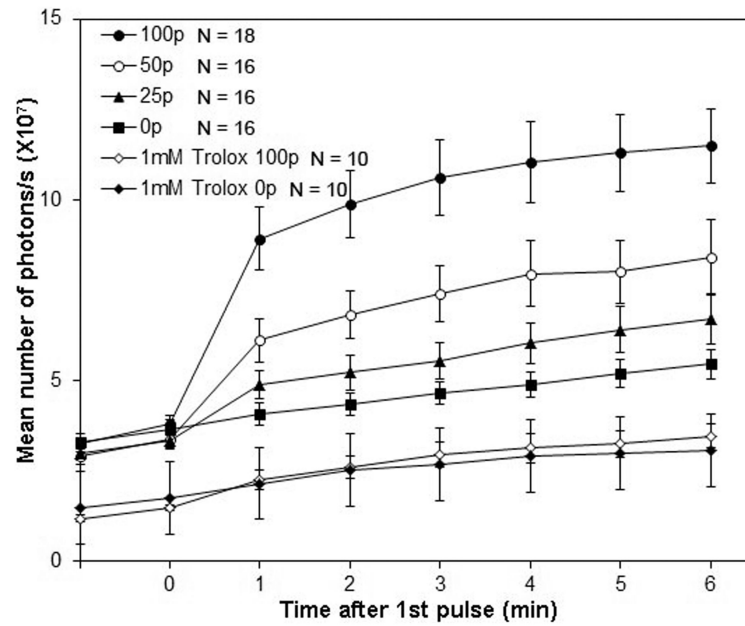

Figure 3. Mean ROS increase following the indicated number of 100 ns pulses at 30 kV/cm. A fluorescence image was captured during a 5 s exposure once every minute. Error bars represent SEM with N=5.

Figure 4.

Ca²⁺-dependence of nsPEF-stimulated ROS fluorescence. For each case, 100 pulses (100 ns, 30 kV/cm) were applied and the fluorescence was measured during 1 second of excitation light exposure to a single cell at the time indicated. The mean background signal was subtracted from each mean measured signal. The probabilities that any of the indicated pairs are not significantly different are indicated by the asterisks: * p < 0.05, **p < 0.01, *** p < 0.001. Each bar represents the mean response of at least four independent experiments and the error bars represent the SEM.
