### Abstract

**Background**—Although chronic kidney disease (CKD) is a highly prevalent condition among older adults with diabetes, the associations between health-related quality of life (HRQOL) and severity of CKD in this population are not well understood. The objective of this study was to assess HRQOL and depressive symptoms across estimated GFR (eGFR) stages.

**Study Design**—Cross-sectional.

**Setting & Participants**—Participants included 5,805 members of Kaiser Permanente Northern California age 60 or older with diabetes from the 2005–2006 Diabetes Study of Northern California (DISTANCE) survey.

**Predictor**—eGFR categories were defined as 90 (referent category), 75–89, 60–74, 45–59, 30–44 or 29 ml/min/1.73m<sup>2</sup>.

**Outcomes**—HRQOL was measured using the modified Short Form 8 Physical Component Summary (PCS) and Mental Component Summary (MCS) scores. Depressive symptoms were measured using the Patient Health Questionnaire 8.

**Results**—In unadjusted linear regression analyses, physical (PCS) and mental (MCS) HRQOL scores were significantly lower with worsening eGFR level. However, after adjustment for sociodemographics, diabetes duration, obesity, and cardiovascular comorbidities, and taking into account interactions with proteinuria, none of the eGFR categories were significantly or substantively associated with PCS or MCS score. In both unadjusted and adjusted analyses, higher risk of depressive symptoms was observed among respondents with eGFR 29 ml/min/1.73m<sup>2</sup>.

(relative risk, 2.02; 95% CI, 1.10–3.71;  $p < 0.05$ ) compared with the referent group. However, this eGFR–depression relationship was no longer significant after adjusting for hemoglobin levels.

**Limitations**—Participants are part of a single health care delivery system.

**Conclusions**—Our findings suggest the need for greater attention to and potential interventions for depression in patients with reduced eGFR.

---

Chronic kidney disease (CKD) is a recognized public health concern with significant associated morbidity and mortality.<sup>1</sup> Nearly one third of community-dwelling adults older than age 70 meet the criteria for CKD when defined as an estimated glomerular filtration rate (eGFR) less than 60ml/min/1.73m<sup>2</sup>.<sup>2</sup> Older adults also experience higher rates of having eGFR <30ml/min/1.73m<sup>2</sup> than younger persons in part due to higher rates of diabetes and hypertension; further, older adults are the fastest growing population of incident dialysis patients.<sup>3</sup>

Decisions about how to manage CKD and when to initiate dialysis are clinically challenging, especially for older patients with diabetes who are more likely to have CKD compounded by high levels of co-morbidity, including depression, cognitive impairment, physical disability, and frailty.<sup>4–7</sup> Maintaining or improving quality of life should be an important consideration in guiding CKD treatment decisions.

Only a small number of studies have described health-related quality of life (HRQOL) or depression in patients with CKD. One previous study by Mujais, et al., showed that in advanced CKD (stages 3–5), physical HRQOL is more often affected than mental HRQOL, and patients with advanced CKD have lower HRQOL scores than the general population.<sup>8</sup> Prior studies that have evaluated depressive symptoms among earlier stages of CKD have shown a high prevalence, some exceeding 50% of the population.<sup>9–12</sup> While these studies have been valuable, the results have limited generalizability due to single center populations, small sample sizes, or a focus on patients in specialized clinics.

We performed a cross-sectional assessment of HRQOL and depressive symptoms across eGFR categories among older adults with diabetes. This research was conducted as part of The Diabetes and Aging Study, an ancillary study to the Diabetes Study of Northern California (DISTANCE) survey. The Diabetes and Aging Study is a collaborative investigation to address significant gaps in existing knowledge regarding the natural history, service use and self-care of a multi-ethnic population of older adults with diabetes.

## Methods

### Study Design

In 2005–2006, the DISTANCE survey collected information about demographics, health behaviors, social support, and patient-provider interactions from a race-stratified, random sample of members of the diabetes registry of Kaiser Permanente Northern California, an integrated healthcare delivery system. The diabetes registry consists of all patients within the Kaiser Permanente Northern California health system with diabetes identified from automated databases of pharmacy data, laboratory data, hospitalization records, and outpatient diagnoses as having diabetes using standardized criteria. The DISTANCE survey yielded 20,188 respondents (62% response rate) based on a standard algorithm from the Council of American Survey Research Organization.<sup>13</sup> Data collection methods have been described in detail previously.<sup>14,15</sup> Survey data were linked to respondents' electronic medical records including laboratory results and medical diagnoses. All laboratory tests were conducted by a single regional laboratory and eGFR was calculated using isotope-dilution mass spectrometry (IDMS) standardized measurements of creatinine.<sup>16</sup> In this

study, we included DISTANCE survey respondents who were age 60 years or older at the time of the survey (baseline) and had at least one eGFR value in the 15 months preceding baseline.

### Exposure of Interest

The exposure of interest was eGFR stage as calculated by the CKD-EPI (KD Epidemiology Collaboration) creatinine equation,<sup>17</sup> adjusted for gender and race. Estimated GFR categories were defined as  $\geq 90$ , 75–89, 60–74, 45–59, 30–44, and  $< 29$  (not receiving dialysis) ml/min/1.73m<sup>2</sup>. The referent group was defined as eGFR  $\geq 90$  ml/min/1.73m<sup>2</sup>. Where possible, the eGFR category was assigned using the last two consecutive eGFR values (separated by at least 3 months) within the 15 months preceding survey response (n=4,255 [73%]). If the two eGFR values were discrepant in terms of category, we assigned the respondent to the higher value eGFR category. If only one eGFR value was available, it alone was used to define eGFR stage (n=1,550 [27%]).

### Outcomes of Interest

**Health-related quality of life—HRQOL** was assessed using an instrument based on the Short Form 8 (SF-8) that includes one question for each domain of the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36). The eight domains are: 1) physical functioning, 2) role limitations due to physical problems; 3) pain; 4) general health; 5) vitality; 6) emotional well-being; 7) role limitations due to emotional problems; and 8) social function.<sup>18</sup> Responses to each question were transformed into SF-36 equivalent scores and overall Physical Component Summary (PCS) and Mental Component Summary (MCS) HRQoL scores were calculated.<sup>19</sup> This instrument is normalized so that in the general population the mean PCS and MCS scores are each 50 points with a standard deviation (SD) of 10 points. In adults 65–74 years of age, the mean PCS is 44.7  $\pm$  9.3 (SD) and MCS is 52.8  $\pm$  8.3 points.<sup>20</sup> At least a one-point difference in SF-36 scores is considered the minimal cutoff point for clinical significance,<sup>21</sup> but differences of 3–5 points have also been suggested.<sup>22</sup> These differences in scores can be illustrated using changes to the first SF-8 question, “Overall, how would you rate your health during the past 4 weeks?” for which the response options are “excellent, very good, good, fair, poor, very poor.” Holding the responses to other questions constant, the difference in score for a response of “excellent” vs. “very good” is approximately one point; the difference in score for a response of “excellent” vs. “good” is approximately three points. For this study, continuous (means) and categorical (lowest quartiles) PCS and MCS scores were the outcomes of interest.

**Depressive symptoms—**Depressive symptoms were assessed using the Patient Health Questionnaire (PHQ-8), an eight-item survey previously validated for use in the primary care setting based on the DSM-IV diagnostic criteria for major depressive disorder.<sup>23,24</sup> The PHQ-8 score ranges from 0 to 24 with scores  $\geq 10$  consistent with depression.<sup>24,25</sup>

**Covariates—**Covariates for this study included self-reported survey data: age, gender, race/ethnicity, marital status, household income, education level and duration of diabetes.<sup>15</sup> For other covariates, we used diagnostic and procedure codes from outpatient and inpatient medical records measures within 15 months of each participant’s survey date. We included obesity categories, defined as underweight (body mass index [BMI],  $< 18.5$  kg/m<sup>2</sup>, normal (BMI, 18.5–24.9 kg/m<sup>2</sup>), overweight (BMI, 25.0–29.9 kg/m<sup>2</sup>), mildly obese (BMI, 30.0–34.9 kg/m<sup>2</sup>), or moderately/extremely obese (BMI,  $\geq 35.0$  kg/m<sup>2</sup>).<sup>26</sup> A history of cardiovascular disease was defined by cerebrovascular disease (ICD-9 codes: 430–438.9), myocardial infarction (codes 410–410.92 and 412), congestive heart disease (codes 428–428.9), or peripheral vascular disease (codes 440.20–440.24, 440.31–440.32, 440.8, 440.9, 443.9, 441–441.9, 785.4, V43.4, and v43.4). Duration of diabetes was defined as time in

years since diagnosis at the time of the survey. The presence of proteinuria was defined either as urinary protein-creatinine ratio  $\geq 200$  mg/g or as 24-hour urinary protein  $\geq 150$  mg per total volume or urinary albumin-creatinine ratio  $\geq 300$  mg/g.

## Statistical Methods

The DISTANCE survey used a stratified random sampling design that over-sampled minority patients to provide adequate power for racial/ethnic contrasts. To account for this sampling design, we weighted analyses using expansion weights (reciprocal of the non-proportional sampling fractions for each ethnic group) in all multivariable models. Additionally, we addressed survey non-response bias in the analysis using the Horvitz-Thompson approach<sup>27</sup> which entailed fitting a model which predicted response to the DISTANCE survey, then creating individual weights (reciprocal of the probability of the observed response) and applying the weights to our statistical models.<sup>28</sup>

We specified multivariable linear regression models to evaluate the association between eGFR category and mean PCS or MCS, and calculated the adjusted means at each eGFR category, keeping all other covariates at their mean values. We then specified modified Poisson regression models with a log link function and robust error variance to directly estimate the 1) relative risk (RR) of scoring in the lowest quartile of PCS or MCS and 2) RR of reporting depressive symptoms as measured by the PHQ-8 (score  $\geq 10$ ).<sup>29</sup> Starting with a base (unadjusted) model, we sequentially introduced blocks of covariates to evaluate their effects on the main exposure variable, eGFR category. Model 1 was unadjusted; Model 2 was adjusted for respondent sociodemographics (age, gender, race/ethnicity, marital status, household income, and education level); Model 3 was adjusted for sociodemographics, obesity, duration of diabetes and proteinuria; and Model 4 was further adjusted for cardiovascular comorbidities. Model 5 was a sensitivity analysis to determine if hemoglobin level accounted for any significant effects observed between eGFR category and HRQOL or depressive symptoms from the fully adjusted Model 4. Finally, we specified models with an added interaction term (eGFR  $\times$  proteinuria) to assess whether the potential effect of eGFR differed for those with versus without proteinuria. When interactions were significant, we then specified stratified models (separate models for those with and without proteinuria).

## Results

### Patient Characteristics

There were 5,805 respondents aged 60 years or older who had an identifiable eGFR measurement and who completed the HRQOL questionnaire. [Figure 1] The distribution of patients in each eGFR category (all in ml/min/1.73m<sup>2</sup>) was as follows: eGFR  $\geq 90$  (referent group), 1,222 (21.1%); eGFR 75–89, 1,513 (26.1%); eGFR 60–74, 1,602 (27.5%); eGFR 45–59, 959 (16.5%); eGFR 30–44, 392 (6.8%); and eGFR  $\leq 29$ , 117 (2.0%) [Table 1]. The mean age was  $67.2 \pm 4.8$  (SD) years, with the youngest mean age among respondents in the referent group. Lower eGFR categories were associated with higher proportions of women and lower household income. Respondents in lower eGFR categories had longer durations of diabetes, higher prevalences of cardiovascular disease and proteinuria, and lower mean hemoglobin levels.

### Physical HRQOL

In unadjusted analyses (Model 1), physical HRQOL scores (PCS) were significantly lower with each eGFR category (except eGFR 75–89 ml/min/1.73m<sup>2</sup>) compared with the referent group of eGFR  $\geq 90$  ml/min/1.73m<sup>2</sup> [Table 2]. This association persisted after adjusting for sociodemographics, duration of diabetes, obesity and proteinuria (Model 3) for respondents with eGFR less than 45 (referent group adjusted mean, 43.97; 95% CI, 43.11–44.83); eGFR

30–44 (adjusted mean, 42.21; 95% CI, 40.98–43.43) and eGFR  $\geq 29$  ml/min/1.73m<sup>2</sup> (adjusted mean, 40.93; 95% CI, 38.73–43.14). However, in the fully adjusted model (Model 4) that additionally adjusted for cardiovascular disease, these differences in adjusted means were no longer significant. The RR of being in the lowest 25<sup>th</sup> percentile of physical HRQOL compared with the referent group was not significantly different in the adjusted models (data not shown). We also detected significant ( $p < 0.001$ ) interactions between eGFR  $\times$  proteinuria, however the lack of relationship between eGFR and PCS persisted in those models with and without proteinuria (data not shown).

### Mental HRQOL

In unadjusted analyses (Model 1), mental HRQOL scores (MCS) were significantly lower only for respondents in the lowest eGFR category of  $\leq 29$  ml/min/1.73m<sup>2</sup> (adjusted mean, 48.18; 95% CI, 46.68–49.68) compared with the referent group eGFR category of  $\geq 90$  ml/min/1.73m<sup>2</sup> (adjusted mean, 50.71; 95% CI, 50.18–51.24;  $p < 0.05$ ) while respondents with eGFR 60–74 ml/min/1.73m<sup>2</sup> had significantly higher MCS scores (adjusted mean, 51.47; 95% CI, 51.05–51.89;  $p < 0.05$ ) [Table 3]. In fully adjusted analyses including sociodemographics, duration of diabetes, obesity, proteinuria and cardiovascular disease (Model 4) only those respondents with lowest eGFR level ( $\leq 29$  ml/min/1.73m<sup>2</sup>) demonstrated significantly lower mean MCS score (48.58; 95% CI, 46.61–50.54;  $p < 0.05$ ) compared to the referent group adjusted mean (50.96; 95% CI, 50.20–51.72;  $p < 0.05$ ), but these findings were not substantive. The RR of being in the lowest quartile of mental HRQOL compared with the referent group in fully adjusted analyses was not significant (data not shown). We also detected significant ( $p < 0.04$ ) interactions between eGFR  $\times$  proteinuria, however the lack of relationship between eGFR and MCS persisted in those models with and without proteinuria (data not shown).

### Depressive Symptoms

In the unadjusted analyses (Model 1), we found that only respondents with the lowest eGFR category ( $\leq 29$  ml/min/1.73m<sup>2</sup>) had a significantly increased risk for depressive symptoms (RR, 2.02; 95% CI, 1.10–3.71;  $p < 0.05$ ) [Table 4]. In the fully adjusted model (Model 4), those respondents with eGFR  $\leq 29$  ml/min/1.73m<sup>2</sup> remained at significantly increased risk of reporting depressive symptoms compared with the referent group with eGFR  $\geq 90$  ml/min/1.73m<sup>2</sup> (RR, 2.04; 95% CI, 1.06–3.91;  $p < 0.05$ ). We detected no significant effect eGFR  $\times$  proteinuria interactions, and thus this strong relationship between eGFR and depression was consistent across those with and without proteinuria.

### Mediation Models

To test the effect of hemoglobin as a potential mediator of any observed relationships between eGFR and HRQOL or depressive symptoms, we added hemoglobin level to the fully adjusted models for MCS and PHQ-8 scores. As expected, after adding hemoglobin to the model for PCS (Table 2, Model 5), there were no significant differences in PCS mean scores for any eGFR categories compared with the referent group, which was not different from the results for the fully adjusted Model 4 (adjusted for sociodemographics, obesity, duration of diabetes, cardiovascular comorbidities and proteinuria). When adding hemoglobin as a covariate for MCS (Table 3, Model 5), we found that respondents with eGFR  $\leq 29$  ml/min/1.73m<sup>2</sup> no longer had significantly lower mean MCS scores (49.04; 95% CI, 46.98–51.11) compared to the referent group with eGFR  $\geq 90$  ml/min/1.73m<sup>2</sup> (mean score, 50.48; 95% CI, 49.54–51.41;  $p = 0.3$ ). When hemoglobin was added to the model for depressive symptoms (Table 4, Model 5), we found that although respondents with eGFR  $\leq 29$  ml/min/1.73m<sup>2</sup> remained at increased risk for depressive symptoms compared with the referent group (RR, 1.72; 95% CI, 0.89–3.33;  $p = 0.1$ ), this result was no longer statistically significant.

## Discussion

This study assessed the relationship between eGFR and HRQOL and depressive symptoms in a population of over 5,800 community-dwelling, insured older adults with diabetes enrolled in Kaiser Permanente Northern California. In this study, we found that after adjustment, there was no substantive relationship between eGFR and physical or mental HRQoL as a whole, or separately among those with and without proteinuria. However, we also found that respondents with the lowest eGFR values (eGFR  $\leq 29$  ml/min/1.73m<sup>2</sup>) had double the risk of depressive symptoms when compared to respondents with the highest eGFR ( $\geq 90$  ml/min/1.73m<sup>2</sup>) in fully adjusted analyses. This strong relationship was observed in those with and without proteinuria. We also found that the relationship between eGFR and depressive symptoms was partially attributable to variation in hemoglobin level.

Our results differ from prior studies that have examined HRQoL among CKD patients and have shown a stronger effect of lower eGFR based on CKD stage for physical HRQOL compared with mental HRQOL.<sup>8,30</sup> Our results are particularly important as they represent a large outpatient primary care population with diabetes, a population not previously evaluated in the literature but a population that carries a high burden of kidney disease. These results, which show no significant relationship between eGFR and physical HRQOL after adjustment for cardiovascular comorbidities, suggest that it may be the increased burden of cardiovascular disease present at lower eGFR levels rather than the kidney function itself that impairs physical function. The negative effects of cardiovascular disease on HRQOL may be due to cardiovascular deconditioning, the side-effects of medications used to treat cardiovascular disease, or the burden of polypharmacy.<sup>15,31</sup>

Our results suggest an independent association between decreased kidney function and an increased risk of depressive symptoms among those with the worst kidney function (eGFR  $\leq 29$  ml/min/1.73m<sup>2</sup>) even in the presence of other common comorbidities including diabetes and cardiovascular disease among older adults. It is possible that those in the lowest eGFR category are experiencing symptoms more directly related to their kidney disease including dyspnea, poor appetite, or fatigue, which might affect depressive symptoms. Moreover, this relationship was partially mediated by hemoglobin level. These results indicate that lower hemoglobin levels, as a result of worsened kidney function (lower eGFR), may account for symptoms such as dyspnea or fatigue, that could in turn influence mood. In addition to symptoms associated with poor kidney function, mediated by lower hemoglobin levels, respondents with low eGFR levels may also experience uncertainty and anxiety about potential impending kidney failure and the need to consider renal replacement therapy that may also affect mood. Depression in CKD has important clinical implications. Young et al, have previously reported that major depression was common among stage 5 CKD patients with diabetes and was associated with an almost tripling in mortality rates.<sup>32</sup>

There are several limitations of this study. First, this is a cross-sectional study of patients with diabetes in a large managed care organization and the findings may be the result of specific care patterns of this health delivery system. For example, all patients had uniform access to primary care with integrated nephrology consult services available. On the other hand, this is a large study of nearly 6,000 insured patients who received care within an integrated health care system. Second, we did not have more than a single eGFR value (in the baseline time period prior to survey response) for about one quarter of our sample. The lack of multiple eGFR records was due to this being a sample of primary care outpatient sample in which laboratory values were obtained during routine clinical care. Therefore, we can only describe our results in terms of eGFR level rather than stage of CKD. In an effort to reduce the likelihood that our sample contained persons with acute kidney injury rather than CKD, we did exclude all respondents with laboratory values obtained in the in-patient or

emergency room settings during the baseline period. The laboratory data presented in this study is representative of that for patients with diabetes in general primary care and therefore, these results have relevance for many patients. Also, we cannot confirm the direction of the relationships between eGFR category, comorbidities, and HRQOL, although reverse causality (poorer HRQOL significantly reducing eGFR) is unlikely. Future studies that evaluate HRQOL in patients prospectively would be able to better define these relationships. Finally, the HRQOL measures in this study did not include kidney disease-specific items, such as those validated in the KDQoL-SF (Kidney Disease Quality of Life) questionnaire or the CHOICE (Choices for Healthy Outcomes in Caring for ESRD) health experience questionnaire, because the original study was aimed at general HRQoL among persons with diabetes.<sup>33–35</sup> However, it is not clear if disease-specific measures would alter significantly our results since such kidney disease-specific questionnaires are validated for use in patients with advanced CKD (stage 4) and not the general population with CKD. The measures used in this study were validated for a population of primary care patients with diabetes.<sup>36</sup> Despite these limitations, we believe that the results of this study provide additional information in an area of great need, the understanding of the relationship between kidney disease, eGFR, HRQOL, and depression.

In summary, among older adults with diabetes, lower eGFR, with and without the presence of proteinuria, was associated with a markedly increased risk of depressive symptoms after accounting for cardiovascular comorbidities. However we found no evidence to support previous reports suggesting a relationship between eGFR and physical or mental HRQOL. Our findings argue for the need for greater attention toward identifying and addressing depressive symptoms among those with decreased kidney function.
