Abstract

The neural pathways through which substance P (SP) influences fear and anxiety are poorly understood. However, the amygdala, a brain area repeatedly implicated in fear and anxiety processes, is known to contain large numbers of SP containing neurons and SP receptors. Several studies have implicated SP neurotransmission within the amygdala in anxiety processes. In the present study, we evaluated the effects of site-specific infusions of a SP receptor antagonist, GR 82334, on conditioned fear responses using the fear-potentiated startle paradigm. GR 82334 infusion into the basolateral (BLA) or the medial (MeA) nuclei of the amygdala, but not into the central nucleus (CeA) of the amygdala, dose-dependently reduced fear-potentiated startle. Similar effects were obtained with GR 82334 infusion into the ventromedial nucleus of the hypothalamus (VMH), to which the MeA projects, and into the rostral dorsolateral periaqueductal gray (PAG), to which the VMH projects, but not into the deep layers of the superior colliculus/deep mesencephalic nucleus (dSC/DpMe), an output of the CeA previously shown to be important for fear-potentiated startle. Consistent with previous findings, infusion of the AMPA receptor antagonist, NBQX, into the dSC/DpMe, but not into the PAG, did disrupt fear-potentiated startle. These findings suggest that multiple outputs from the amygdala play a critical role in fear-potentiated startle and that SP plays a critical, probably modulatory role, in the MeA to VMH to PAG to the startle pathway based on these and data from others.

Introduction

A large number of studies have implicated Substance P (SP) in fear and anxiety based on the ability of local infusion of SP into various parts of the brain to elicit defensive and anxiety like effects and that SP antagonists can have anxiolytic effects (cf., Rosenkranz 2007). SP appears to influence affective behaviors, at least in part, by actions within the amygdala (Boyce et al 2001; Ebner et al 2004; Kramer et al 1998; Smith et al 1999). Importantly,

however, SP containing neurons and SP receptors are heterogeneously distributed within this area. Neuronal immunoreactivity for SP is intense in the medial nucleus of the amygdala (MeA), scarce in the central nucleus of the amygdala (CeA) and undetectable in the basolateral nucleus (BLA) of the amygdala (Castellano and McGaugh 1989; Damalama and Swann 1993; Emson et al 1978; Malsbury and McKay 1989; Ribeiro-da-Silva and Hokfelt 2000; Roberts et al 1982). “Although the medial amygdaloid nucleus displays one of the heaviest concentrations of SP-IR terminals in the CNS, most of this immunoreactivity is of local origin... as demonstrated by local knife cuts (Emson et al., 1978).” (p. 265, Ribeiro-da-Silva and Hokfelt 2000). On the other hand, SP receptor immunoreactivity is moderately dense in both the MeA and the CeA (Mantyh 2002; Boyce et al., 2001; Saffroy et al., 1988) and less intense in the BLA (Levita et al 2003; Saffroy et al 1988; Smith et al 1999). These expression patterns suggest a differential involvement of amygdaloid nuclei in SP-mediated affective behaviors. In fact, increases in SP mRNA and SP release induced by emotional stressors have been found in the MeA, but not in the CeA (Ebner et al 2004; Sergeev et al 2005), and an increase in SP receptor internalization, a marker of SP release, was found in the BLA (Kramer et al 1998; Smith et al 1999). Direct infusion of SP into the MeA was shown to be anxiogenic in the elevated plus maze test (Ebner et al 2004), and infusion of a SP receptor antagonist into the BLA blocked maternal separation-induced vocalization (Boyce et al 2001). These data suggest that the MeA and the BLA, but perhaps not the CeA, are important neural substrates through which SP modulates or mediates affective behaviors. However, because of differences in methodology between these studies and limited data for the CeA, the current paper examined the contribution of SP neurotransmission in each of these areas by infusing the SP receptor antagonist GR 82334 into the BLA, the MeA or the CeA just prior to testing in the fear-potentiated startle paradigm.

We also investigated the possible neural substrates involved with SP's role in fear-potentiated startle outside the amygdala. Fear-potentiated startle is mediated by the CeA and its projection to the deep layers of the superior colliculus/deep mesencephalic nucleus (dSC/DpMe) of the rostral midbrain and subsequently to the primary startle reflex circuit in the brainstem (Davis et al 1993; Davis et al 1997; Hitchcock and Davis 1991; Meloni and Davis 1999; Rosen et al 1991; Franklin and Yeomans, 1995; Zhao and Davis 2004). In addition, we recently reported that fear-potentiated startle also is blocked by infusion of the AMPA receptor antagonist NBQX into the MeA (Walker et al 2005). It is unclear how the MeA influences fear-potentiated startle as it does not project directly to the startle reflex circuit, or the dSC/DpMe, or the CeA (Canteras et al 1995). However, the MeA does have heavy projections to the ventromedial nucleus of the hypothalamus (VMH) and this pathway was found to contain SP (Canteras et al 1994; Canteras et al 1995; Han et al 1996; Shaikh et al 1993). Lesions of the VMH have been shown to disrupt other affective behaviors (Colpaert and Wiepkema 1976; de Oliveira et al 1997; Dielenberg et al 2001; Han et al 1996; Sudakov 1987). Moreover, SP containing afferents from the VMH project to the periaqueductal gray (PAG - Dornan, 1990), that in turn projects to the pontine startle reflex circuit (Cameron et al 1995; Canteras et al 1994; Fendt et al 1994; Meloni and Davis 1999; Siegel et al 1997). Thus, it is conceivable that the SP containing MeA->VMH->PAG->pontine circuit may participate in or be required for the full expression of fear-potentiated startle. To evaluate this possibility, we also infused GR 82334 into the VMH, the PAG, as well as the dSC/DpMe, prior to fear-potentiated startle testing.

Materials and Methods

Subjects

Male Sprague-Dawley rats (Charles River, Raleigh, NC), weighing 400–450 g at the time of surgery, were used in this study. Animals were housed in groups of two in plastic cages and maintained on a 12-hour light-dark cycle (light 8:00-8:00) with food and water available ad

libitum. We affirm that the original studies reported in this paper have been carried out in accordance with the Guide for the Care and Use of Laboratory Animals as adopted and promulgated by the National Institutes of Health.

Cannula Implantation

Before the behavioral experiments, rats were anesthetized with Nembutal (sodium pentobarbital, 50 mg/kg i.p., Emory University School of Medicine Pharmacy, Atlanta Georgia) and placed in a Kopf stereotaxic instrument (Model 900, Tujunga, CA) with blunt ear bars. The skull was exposed and stainless steel guide cannulas (22 gauge, Plastics One, Roanoke, VA), which were occluded with an internal dummy stylet extending 1 mm beyond the guide cannula tip, were bilaterally lowered into the brain aiming at the MeA (AP= -2.8 mm, ML= +/-3.5 mm and DV= -8.5 mm), the CeA (AP= -2.6 mm, ML= +/-4.2 mm and DV= -8.5 mm), the BLA (AP= -2.8 mm, ML= +/-5.1 mm and DV= -8.4 mm), the VMH (AP= -3.2 mm, ML= +/- 0.7 mm and DV= -9.4 mm), the dorsomedial nucleus of the hypothalamus (DMH, AP= -3.2 mm, ML= +/-0.7 mm and DV= -8.4 mm), the rostral dorsolateral PAG (AP= -6.4 mm, ML= +/-0.5 mm and DV= -5.0 mm), the caudal ventrolateral PAG (AP= -7.7 mm, ML= +/-0.6 mm and DV= -6.0 mm), and the dSC/ DpMe (AP= -6.4 mm, ML= +/- 1.5 mm and DV= -5.1 mm). The AP and ML positions were measured with respect to bregma and midline respectively and the DV position was measured with respect to dura above the implantation site with the exception of the CeA and the BLA for which the DV position was measured with respect to the surface of the skull at bregma. The cannulas were anchored with dental cement to four jeweler screws that were previously attached to the skull. Animals were allowed to recover from the surgery for at least 7 days prior to behavioral procedures.

Startle Apparatus

Rats were trained and tested in four identical stabilimeters located in separate chambers (90 × 70 × 70 cm) that were dark, ventilated, and sound attenuated. Each stabilimeter consisted of an 8 × 15 × 15 cm Plexiglas and wire mesh cage, and was suspended within a steel frame by four compression springs. The floor of each cage consisted of four stainless steel bars (6 mm in diameter and 18 mm apart), through which footshocks were delivered. An accelerometer (PCM Piezotronics, Depew, NY) was affixed to the bottom of the cage to detect any movement of the cage. The displacement of the accelerometer caused by cage movement generated a voltage that was integrated and proportional to the velocity of cage movement. The analog output of the accelerometer was amplified (PCB, Piezotronics, Model 483B21) and digitized on a scale of 0–2500 units by an InstruNET device (GW Instruments, Model 100B, Somerville, MA) interfaced to a Macintosh G3 computer. The amplitude of startle response was defined as the maximal peak-to-peak voltage that occurred during the first 200 msec after onset of the startle-eliciting stimulus. The 200-msec sampling window allows the highest peak-to-peak movement of the cage to be accurately sampled (Cassella and Davis 1986). A surveillance camera (Burle, Model TC 651B with a TC 9907a lens, Operational Security Systems, Atlanta, GA) was positioned behind each stabilimeter and connected to a TV monitor located outside the chamber. Background illumination was provided by a red incandescent bulb (7.5 W) located 11 cm above the stabilimeter.

A high-frequency speaker (Radio Shack Super-tweeters, range 5–40 kHz) was positioned 5 cm from the front of each stabilimeter. Constant background white noise (60 dB) was generated by a General Radio noise generator (ACO Pacific, Inc, Belmont, CA) and delivered through the speaker. The startle-eliciting stimulus was a 50-ms white noise burst (5 ms rise-decay) that was generated by the Macintosh G3 computer (0–22 kHz) and delivered through the same speaker to evoke a startle response. The background noise and the white-noise burst were amplified by a Radio Shack amplifier (100 W, Model MPA-200).

The intensity of the sounds was frequently calibrated with a sound-level meter (Bruel & Kjaer, Model 2235, Marlborough, MA) at a distance that approximated the distance of the rat's ear to the speaker.

The visual conditioned stimulus (CS) was a 3.7-sec light (70 lux) produced by an 8 W fluorescent bulb (100- μ s rise time, measured by a photocell connected to a storage oscilloscope) that was located 15 cm behind each stabilimeter. The unconditioned stimulus (US) was a 0.5-sec, 0.4 mA shock produced by four LeHigh Valley shock generators (SGS-004, LeHigh Valley, Beltsville, MD) located outside the chamber and delivered to the floor bars of each stabilimeter. Shock intensity was measured with a 1-K Ω resistor across a differential channel of an oscilloscope in series with a 100-k Ω resistor connected between adjacent floor bars within each stabilimeter. Current was defined as the root mean square voltage across the 1-k Ω resistor where mA equaled $0.707 \times 0.5 \times$ peak-to-peak voltage. The presentation and sequencing of all stimuli were under the control of the Macintosh G3 computer using specially designed software (The Experimenter, Glassbeads Inc., Newton, CT).

Behavioral Procedures and drug administration

Baseline Startle Test—On two consecutive days, animals were placed in the stabilimeter devices for 5 min without exposure to startle stimuli (acclimation period), followed by 15 startle eliciting noise bursts that were given in a semirandom order, 5 at each of three different intensities (95, 100 and 105 dB), with an interstimulus interval (ISI) of 30 sec. These initial noise bursts were used to familiarize the rats to the acoustic stimuli and were not used for statistical analysis. Immediately after, 45 additional noise bursts were presented, 15 at each of the three aforementioned intensities with a 30-sec ISI. The startle amplitudes across these 45 stimuli were used to divide rats into different test groups such that each group had equivalent mean startle amplitudes.

Fear conditioning training—Twenty four hours after the baseline startle test, rats were given two sessions of training, 24 hrs apart. In each of the training sessions, rats were placed in the stabilimeter devices and 5 minutes later animals were given 10 light-shock pairings that consisted of a 3.7-sec light and a 0.5-sec, 0.4 mA footshock that coterminates with the light. The mean intertrial interval (ITI) was 3 min (range 2 to 4 min). Rats were returned to their home colony after completion of the training session.

Drug administration—Forty-eight hours after training, rats were bilaterally infused with either 0.2, or 1.0, or 6.0 nmoles (depending on the infusion site) of the SP receptor antagonist GR 82334 (Tocris Bioscience, Missouri) or artificial cerebrospinal fluid (ACSF - 130 mM NaCl; 3.5 mM KCl; 1.10 mM KH_2PO_4 ; 1.3 mM MgCl_2 ; 2.5 mM CaCl_2 ; 30 mM NaHCO_3 ; and 5.0 mM glucose). During the infusion, rats were placed in individual plastic cages (28 \times 17 \times 12 cm), the dummy styletes removed and the infusion cannulas inserted (28 gauge, 1 mm projection from the tip of the guide cannula, Plastics One). The infusion cannulas were attached to Hamilton microsyringes (10 μ l, Reno, NV) by polyethylene tubing, and the drug solutions were delivered into the designated brain regions by a Harvard Apparatus pump (Model 22, South Natick, MA) at 0.25 μ l/min for 2 min for a total 0.5 μ l of drug solution in each infusion site. The infusion cannulas remained in place for an additional 2 min, after which they were removed and the dummy styletes replaced.

Fear-potentiated startle testing—Immediately after the infusion, rats were returned to the stabilimeters, where, after 5 min of acclimation, they were presented with 15 noise bursts identical to those in the baseline startle test. The response to these initial noise bursts was not used for statistical purposes. Following these initial noise bursts, 30 additional noise

bursts (10 each at 95, 100, and 105 dB) were presented in the presence of the light (light-noise trials, LN) and 30 were presented in the absence of the light (noise-alone trials, NA) at an ISI of 30 seconds. On the light-noise trials, the startle stimulus occurred 3.2 sec after the onset of the light, the same time point when the footshock had been delivered during training. The light-noise and noise-alone trials were presented in a balanced, pseudorandom order with the constraint that each trial type occurred only once in each consecutive 6-trial block (light-noise or noise-alone \times 95 dB, 100 dB and 105 dB).

Three days after the test session, rats with cannulations in the PAG or the dSC/DpMe were given one short re-training session consisting of 5 pairings of light and footshock with a 3-minute ITI. During the intertrial intervals, 10 noise bursts, 5 at each of 95 and 100 dB, were presented with a 60-sec ISI. These noise bursts were used to minimize the possibility that the rats would learn to discriminate between training and test sessions based on the absence vs. presence of noise bursts. Twenty-four hours later the animals were infused with the AMPA receptor antagonist NBQX (disodium by Tocris, Avonmouth, Bristol, UK) or the opioid receptor agonist morphine sulfate (Sigma-Aldrich, St. Louis, MO) and retested. We found that the retrained non-naïve rats that were previously trained and subsequently infused with drug showed similar fear conditioning and drug response as did naïve rats (Meloni and Davis 1999; Zhao and Davis 2004).

Histological verification of cannula placement

At the end of the experiments, rats were deeply anesthetized by inhalation of Isoflurane, USP (Halocarbon, NJ) and were intracardially perfused with 0.9% saline followed by 8% buffered formalin. The brains were removed from the skull and immersed in a 30% sucrose-formalin solution for at least 3 days. Forty- μ m coronal sections through the cannula track were prepared and every third section was mounted on gelatin-coated slides, air-dried and stained with cresyl violet. The location of the cannulas was assessed under a light microscope and transcribed onto a brain atlas (Paxinos and Watson 1997).

Statistical Analyses

Startle response amplitudes on either the noise-alone trials or the light-noise trials were averaged across the three noise burst intensities and served as the primary dependent variable (i.e. one noise-alone and one light-noise value for each rat). The difference in startle amplitude between the noise alone and light-noise trials (between-trial difference) was also calculated as an additional dependent variable. Startle amplitude was analyzed using a two-way ANOVA (SPSS statistics package, Chicago, IL) with trial type (noise-alone vs. light-noise) and treatment group (dose) as within- and between-subject factors, respectively. Additionally one-way ANOVA followed by post hoc Dunnett's tests (two-sided) was used to compare the difference between the vehicle group and the drug-treated groups.

Results

Cannula Placement

Figure 1 and 2 depict the cannula placements determined by the location of the tips of dummy cannulas. As shown in Figure 1, the cannulas were implanted into the medial nucleus of the amygdala (MeA, the light gray circles), the central nucleus of the amygdala (CeA, the light gray squares), the basolateral nucleus of the amygdala (BLA, the dark-gray circles), the ventromedial nucleus of the hypothalamus (VMH, the light open circles). Data from rats with cannulas that missed these areas were not included in the statistical analyses. Cannula implantations in the midbrain, as shown in Figure 2, included the rostral dorsolateral PAG (rostral dIPAG, the dark-gray circles), the caudal ventrolateral PAG (caudal vIPAG, the black circles) and the dSC/DpMe (the dark gray squares). The location

of the dSC/DpMe was described previously (Zhao and Davis 2004), and includes the deep white and gray layers of the superior colliculus (DpG and DpWh in Paxinos and Watson 1997) and the dorsal part of the deep mesencephalic nucleus.

Role of Substance P in the amygdala on the expression of fear-potentiated startle

In general, the ACSF-treated rats showed an increased startle response in the presence of the light cue that previously had been paired with a footshock. As shown in Figure 3, startle amplitude was higher on light noise (open bar) than on noise alone trials (closed bar) in the vehicle-treated animals. However, fear-potentiated startle was dose-dependently reduced by the substance P receptor antagonist, GR 82334, infused bilaterally into the MeA and the BLA, but not into the CeA. ANOVA revealed a significant main effect of trial type (noise-alone vs. light-noise) for the MeA ($F(1, 31)=29.47, p<0.001$), the BLA ($F(1, 21)=23.43, p<0.001$) and the CeA ($F(1, 28)=24.75, p<0.001$) groups. In addition, the trial type by treatment interaction was also significant for the MeA ($F(2,31)=5.49, p<0.01$) and BLA groups ($F(2,21)=6.77, p<0.01$), but not for the CeA group ($F(2,28)=1.02, p>0.05$). Moreover, Dunnett's tests on the difference scores (i.e., LN minus NA startle amplitude) indicated significant differences between the vehicle and high dose GR 82334 groups that received infusions into the MeA ($p<0.01$) or BLA ($p<0.05$), but not into the CeA ($p>0.05$).

Role of Substance P in the medial hypothalamus on the expression of fear-potentiated startle

Infusion of 1.0 nmole of GR 82334 into the medial hypothalamus did not disrupt fear-potentiated startle (Figure 4). When the dose was increased to 6.0 nmoles, the expression of fear-potentiated startle was blocked with infusion into the VMH. However, when infused into the DMH, it was immediately noticed that this caused remarkable locomotor changes that included severe body flipping, rotation and bending of the head forward. These deficits were not seen with infusion into the VMH. We have frequently observed that profound locomotor changes caused by drug infusion into certain brain areas interfere with the expression of fear-potentiated startle. Thus, GR82334 infusions into the DMH were terminated. With respect to the VMH, ANOVA revealed a significant main effect of trial type ($F(1,28)=24.75, p<0.001$) and a significant trial type by treatment interaction ($F(2,28)=3.36, p<0.05$), and Dunnett's tests indicated significant differences between the vehicle group and the 6-nmol group ($p<0.01$).

Role of Substance P in the midbrain on the expression of fear-potentiated startle

Infusion of 1 nmol GR 82334 into the rostral dIPAG (Figure 5, upper panel) abolished fear-potentiated startle. Statistically, this was indicated by an ANOVA which revealed a significant trial type by treatment interaction, $F(1,12)=6.87, p<0.05$. Anatomical specificity was indicated by the ineffectiveness of infusions into two nearby areas. Specifically, infusion of the same dose into the caudal vIPAG (Figure 5, middle panel) had no effect on fear-potentiated startle (trial type by treatment interaction - $F(1,16)=0.72, p>0.05$), nor did infusion into the dSC/DpMe (trial type by treatment interaction - $F(1,10)=0.92, p>0.05$), which is approximately 1 mm lateral to the rostral dIPAG (Figure 5, lower panel).

Our laboratory previously found that infusion of the AMPA receptor antagonist NBQX into the dSC/DpMe, but not the rostral dIPAG, blocks fear-potentiated startle (Zhao and Davis 2004). Recently we also found that infusion of the opioid receptor agonist morphine into the caudal vIPAG similarly blocks potentiated startle (M. Davis, Y. Yang, Z. Zhao, C-J. Shi - unpublished observations). Therefore, as a positive control for the negative effect of GR 82334 in these two areas, these rats were retrained, and retested with infusions of NBQX into the dSC/DpMe or into the rostral dIPAG, or with infusion of morphine into the caudal vIPAG. The results are shown in Figure 6. As depicted in the upper and the middle panels,

infusion of NBQX (0.79 nmoles) into the dSC/DpMe, but not the rostral PAG blocked fear-potentiated startle (trial type by treatment interactions - for the dSC/DpMe infusions, and $F(1,12)=0.052$, $p>0.05$ for the rostral dlPAG infusions, respectively) and morphine infusions (20 nmole) into the caudal vlPAG were similarly effective (trial type by treatment interaction - $F(1,14)=5.86$, $p<0.05$, lower panel).

Discussion

Blockade of substance P receptors in the MeA and the BLA severely disrupted fear-potentiated startle, whereas similar doses in the CeA had no detectable affect, consistent with the existing literature. Ebner et al. (2004) showed that immobilization stress caused a significant increase in SP release within the MeA but not the CeA. They also found that intra-MeA SP infusions produced anxiety-like behaviors as assessed with elevated plus maze, an effect similar to that induced by immobilization. In the BLA, immobilization or maternal separation produced an increase in SP receptor internalization, a marker of SP release (Boyce et al 2001; Smith et al 1999), and intra-BLA infusion of a SP receptor antagonist significantly attenuated separation-induced vocalizations (Boyce et al 2001).

It is widely believed that conditioned fear stimuli activate BLA projection neurons which send afferents to various downstream target areas such as the CeA and MeA (Davis 1992) (LeDoux 1992). Activation of substance P receptors leads to postsynaptic excitation via G-protein coupled SP receptors which stimulate phospholipase C and adenylate cyclase (Mitsuhashi et al 1992; Otsuka and Yoshioka 1993; Takeda et al 1992). Our finding that fear-potentiated startle could be blocked by infusing a SP receptor antagonist into the BLA suggests that substance P receptor activation contributes to, or is required for activation of BLA projection neurons. Interestingly, however, it has been found that SP receptors in the BLA are largely, if not exclusively, expressed in interneurons (Levita et al 2003; Maubach et al 2001). Application of SP onto BLA slices induces excitation of these interneurons and this, in turn, hyperpolarizes adjacent projection neurons via GABA_A receptors (Maubach et al 2001). By interfering with the normal balance between excitation and inhibition, a substance P receptor antagonist may sufficiently alter network properties so as to disrupt the normal response to fear-signaling stimuli.

One target of BLA output neurons is the MeA. Although there are reciprocal connections between the BLA and MeA (Pitkanen et al 1997), the fact that sensory inputs converge in the BLA but not in the MeA (Jolkkonen et al 2001; LeDoux 2000; Shi and Davis 2001) suggests that, for fear expression, the MeA may function primarily as an output structure which responds to fear-related signals arriving from the BLA. Our previous findings that pre-training infusions of NBQX into the BLA, but not into the MeA, blocked fear learning whereas pre-test infusions into both structures blocked fear expression are consistent with this view (Walker et al 2005). Given that BLA projection neurons are largely glutamatergic (Smith and Pare 1994) and that there are few SP-containing neurons in the BLA (Ribeiro-da-Silva and Hokfelt 2000; Roberts et al 1982), it is reasonable to assume that neurotransmission between the BLA and the MeA is primarily glutamatergic, and not tachykininergic. A double labeling study using a retrograde tracer injected into the MeA combined with immunostaining for SP would be an important initial step in identifying the site of origin of SP-inputs to the MeA that participate in fear expression. The MeA itself contains a large number of neurons that contain substance P, and it is possible that NK1 receptors in the MeA are responding, at least in part, to locally released substance P. Speculatively, substance P neurons within the MeA may be activated by glutamatergic projections from the BLA.

The CeA is also a major recipient of BLA projections and is believed to play an important role in fear-potentiated startle, based partly on evidence that CNQX or NBQX infusions into the CeA block fear-potentiated startle (Kim et al 1993; Walker and Davis 1997). However, in the present study doses of GR 82334 that blocked fear-potentiated startle when infused into the BLA or the MeA, did not significantly disrupt fear-potentiated startle when infused into the CeA. Insofar as the CeA is situated immediately medial to the BLA and just lateral and dorsal to the MeA, this negative finding serves as an important control in establishing that the effect of GR 82334 infusions into the BLA or MeA were mediated locally and not by diffusion to nearby areas. Of course, it is possible that higher doses might have affected fear-potentiated startle. However, pilot data from several animals which received intra-CeA infusions of 5 nmoles of GR 82334 revealed marked locomotor effects which precluded an analysis of fear-potentiated startle.

Early studies have shown that the VMH also is involved in fear and anxiety (Colpaert and Wiepkema 1976; de Oliveira et al 1997; Dielenberg et al 2001; Han et al 1996; Sudakov 1987) and, interestingly, the VMH itself receives a heavy SP-containing input from the MeA (Petrovich et al 2001; Shaikh et al 1993). In fact, this pathway has previously been shown to be critical in mediating defensive rage and predatory attack in cats (Han et al 1996; Shaikh et al 1993). We found that GR 82334 infusions into the VMH also blocked fear-potentiated startle. It is possible that SP-containing neurons in the MeA use the VMH as a relay through which the influences of the MeA on fear-potentiated startle are mediated. It should be noted however that a higher dose of GR 82334 was required in the VMH compared to the BLA or the MeA. This may be due, in part, to the differential expression of SP receptor subtypes in the amygdala versus hypothalamus. Thus, both septide and non-septide-sensitive SP receptors are expressed in the amygdala and activation of either induces intracellular signaling. However, in the hypothalamus the primary SP receptors are the non-septide-sensitive SP receptors to which GR 82334 has a lower affinity (Beaujouan et al 2000). Therefore a higher dose of GR 82334 may be required to block SP neurotransmission in the VMH.

A role for the PAG in mediating fear and anxiety has also been well documented (Bandler and Shipley 1994; Blanchard et al 1981; DeOca et al 1998) and SP neurotransmission has been implicated here as well (De Araujo et al 1999; Gregg and Siegel 2003; Mongeau et al 1998). The findings of our study support a critical role of SP neurotransmission within the PAG in fear-potentiated startle and indicate more specifically that these effects may be mediated primarily by SP receptors in the rostral dIPAG. Perhaps not by coincidence, this is a region that receives a dense projection from the VMH (Bandler and Shipley 1994; Canteras et al 1994; Siegel et al 1997), and approximately 30% of these projections contain substance P (Dornan et al 1990). However, the projections outlined in this paper went to a significantly more caudal region of the dIPAG than was targeted by any of the injections performed as part of the present study. Thus, it is possible that SP release from VMH terminals in the PAG is critically involved in the expression of fear-potentiated startle. However, it is also possible that local SP circuit neurons in the PAG are involved instead and/or as well. The VMH also projects to the vIPAG, particularly to its more caudal elements (Canteras et al 1994), but it is unknown whether these projections also contain substance P. Although SP receptors are distributed throughout the PAG (Barbaresi 1998; Commons and Valentino 2002), our data indicate that those in the caudal vIPAG play a less significant role in fear-potentiated startle.

At the present time it is not clear why SP antagonists infused into the BLA, MeA, VMH and PAG so completely block fear-potentiated startle. There are at least two major questions in this regard. First, it is not clear how inactivation of apparently parallel neural pathways (e.g. BLA->CeA->dSC/DpMe and BLA->MeA->VMH ->PAG) each completely block the

expression of fear-potentiated startle. Instead, one might expect that either pathway could mediate fear-potentiated startle alone and so that inactivation of points along both pathways, rather than just one, would be required to totally block fear-potentiated startle. Secondly, it is not clear how SP might be acting in the BLA, MeA, VMH and PAG to affect fear-potentiated startle. Although local infusion of SP into each of these sites can produce defensive and anxiety-like behaviors we did not see any increase in startle when we infused SP into the MeA over a very wide range of doses (Z. Zhao, Y. Yang and M. Davis, unpublished observations). Indeed, at high doses, SP actually interfered with fear-potentiated startle, perhaps via internalization of the SP receptor. However, the inability of SP to facilitate startle does not necessarily rule out the idea that release of SP is involved in mediating fear-potentiated startle because we clearly cannot recreate the temporal dynamics of endogenous SP release by flooding the system with exogenous SP.

In a long series of pilot studies (Y. Yang and M. Davis, unpublished) we were not able to demonstrate convincingly a serial circuit from the MeA to VMH vis-a-vis SP. For example, although local infusion of GR 82334 into the left MeA or right VMH (or vice versa) by themselves did not fully block fear-potentiated startle, infusion into the left MeA and right VMH did, consistent with a serial circuit. However, equivalent doses of GR 82334 into the left MeA and the left VMH together also did, inconsistent with a serial process. It is thus possible that SP plays a more permissive role in these structures. For example, in the spinal cord, SP has no effect by itself, but is a powerful modulator of both NMDA- and AMPA-mediated excitation of nociceptive neurons in the spinal cord (Budai et al., 1992).

Taken together with findings from our laboratory and elsewhere, we propose that fear-potentiated startle is mediated by the amygdala through two separate neural pathways (see Figure 7). The first one originates in the CeA and connects to the PnC via a synapse in the dSC/DpMe of the rostral midbrain. This pathway appears to rely primarily on ionotropic glutamatergic transmission at the dSC/DpMe. The second pathway, as suggested by the findings reported here, originates in the MeA and may access the primary startle reflex circuit using relays located in the VMH and rostral dIPAG. This pathway appears to require NK1 receptor activation. Interestingly, blockade of glutamate receptors (Zhao and Davis 2004) or activation of GABA-A receptors (Meloni and Davis 1999) in the dSC/DpMe, or blockade of substance P receptors or activation of opioid receptors (M. Davis, Z. Zhao, Y. Yang, C-J. Shi, in preparation) in the MeA, VMH and PAG each totally blocks the expression of fear-potentiated startle. Thus, although these pathways represent parallel outputs connecting the amygdala with the PnC, collectively the data suggest that activation of each is necessary for the expression of fear-potentiated startle under normal circumstances. In addition, anatomically, the CeA projects directly to the PnC based on anterograde and retrograde tracing (Rosen et al, 1991), indicating a third pathway might also be involved in the expression of fear-potentiated startle. However, to date there is no direct evidence this pathway is actually involved because its role was tested using electrolytic lesions at various levels along this pathway (Hitchcock and Davis, 1991) which could have interfered with the indirect pathways via the dSC/DpMe or the VMH and PAG.

Finally, SP also plays an important role at the level of the PnC in the startle pathway. Kungel et al., (1994) found that acoustically responsive neurons in the PnC showed a marked increase in firing rate following iontophoretic injection of SP and local infusion of SP into the PnC caused a dose-dependent increase in startle amplitude (Krase et al., 1994). This increase in startle, as well as shock sensitization of startle, was blocked by local infusion of a SP antagonist here. In this case the source of SP appears to come from the laterodorsal tegmental nucleus and the pedunculopontine tegmental nucleus (Kungel et al., 1994).

Acknowledgments

This research was supported by National Institute of Mental Health grants MH47840, MH57250 and MH59906, and the Science and Technology Center (The Center for Behavioral Neuroscience of the National Science Foundation under Agreement No. IBN-9876754) and the Yerkes Base Grant.

However, Dr. Michael Davis does have a project on a grant from the NIMH (U19 MH06905602) to test compounds supplied by Glaxo Smith Kline, one of the which is a NK1 antagonist.

Biography

Michael Davis

SAB Helicon Corp – now terminated

Consultant – Repligen Corp – 2002–2005

Consultant –Amgen Corp: Jan 2, 2004

Consultant –AstraZeneca: June 6, 2006

Consultant – Tikvah Therapeutics, Inc. 2007-present

Research support – Repligen Corp – 2002–2005

Research support – AstraZeneca

Unrestricted gift - AstraZeneca

Dr. Davis has a patent pending for the use of cognitive enhancers, in particular, D-cycloserine, to be used as an adjunct to psychotherapy. Tikvah Therapeutics, Inc. has licensed this technology to commercialize the use of D-cycloserine as an adjunct to psychotherapy. He is a partner in a company called Therapade and received a signing fee and then will receive certain milestone payments over the next several years. Once the indication is approved by the FDA he is entitled to royalties.

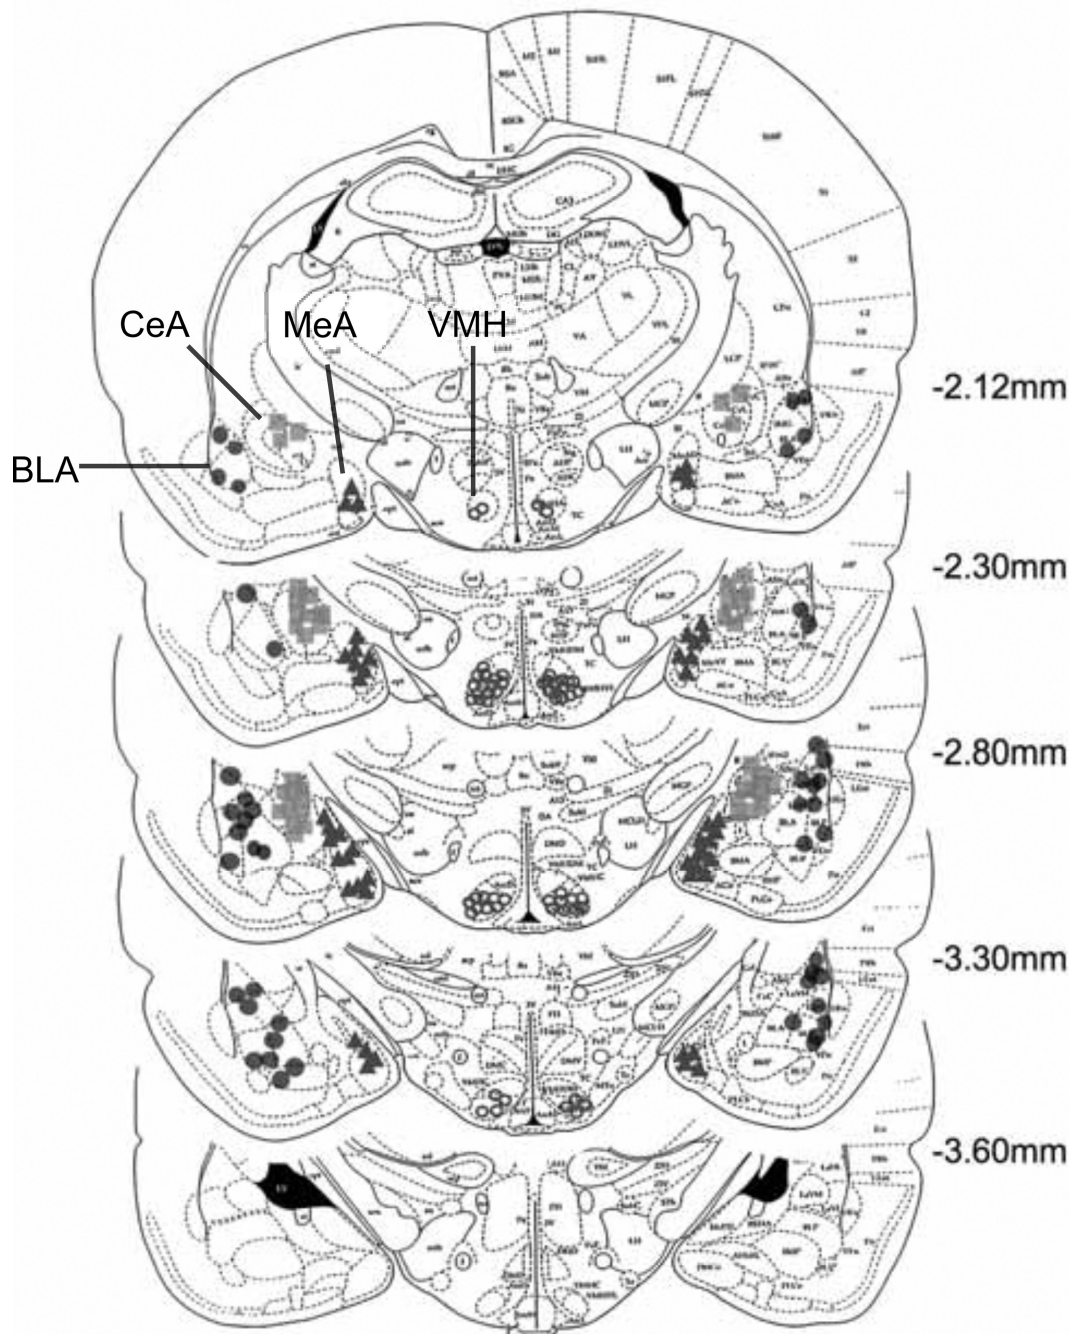

Figure 1. Cannula locations for different rats implanted with cannulas in the central nucleus of the amygdala (CeA); basolateral nucleus of the amygdala (BLA); medial nucleus of the amygdala (MeA) or the ventral medial nucleus of the hypothalamus (VMH). (Plates adapted from Paxinos and Watson, 1997).

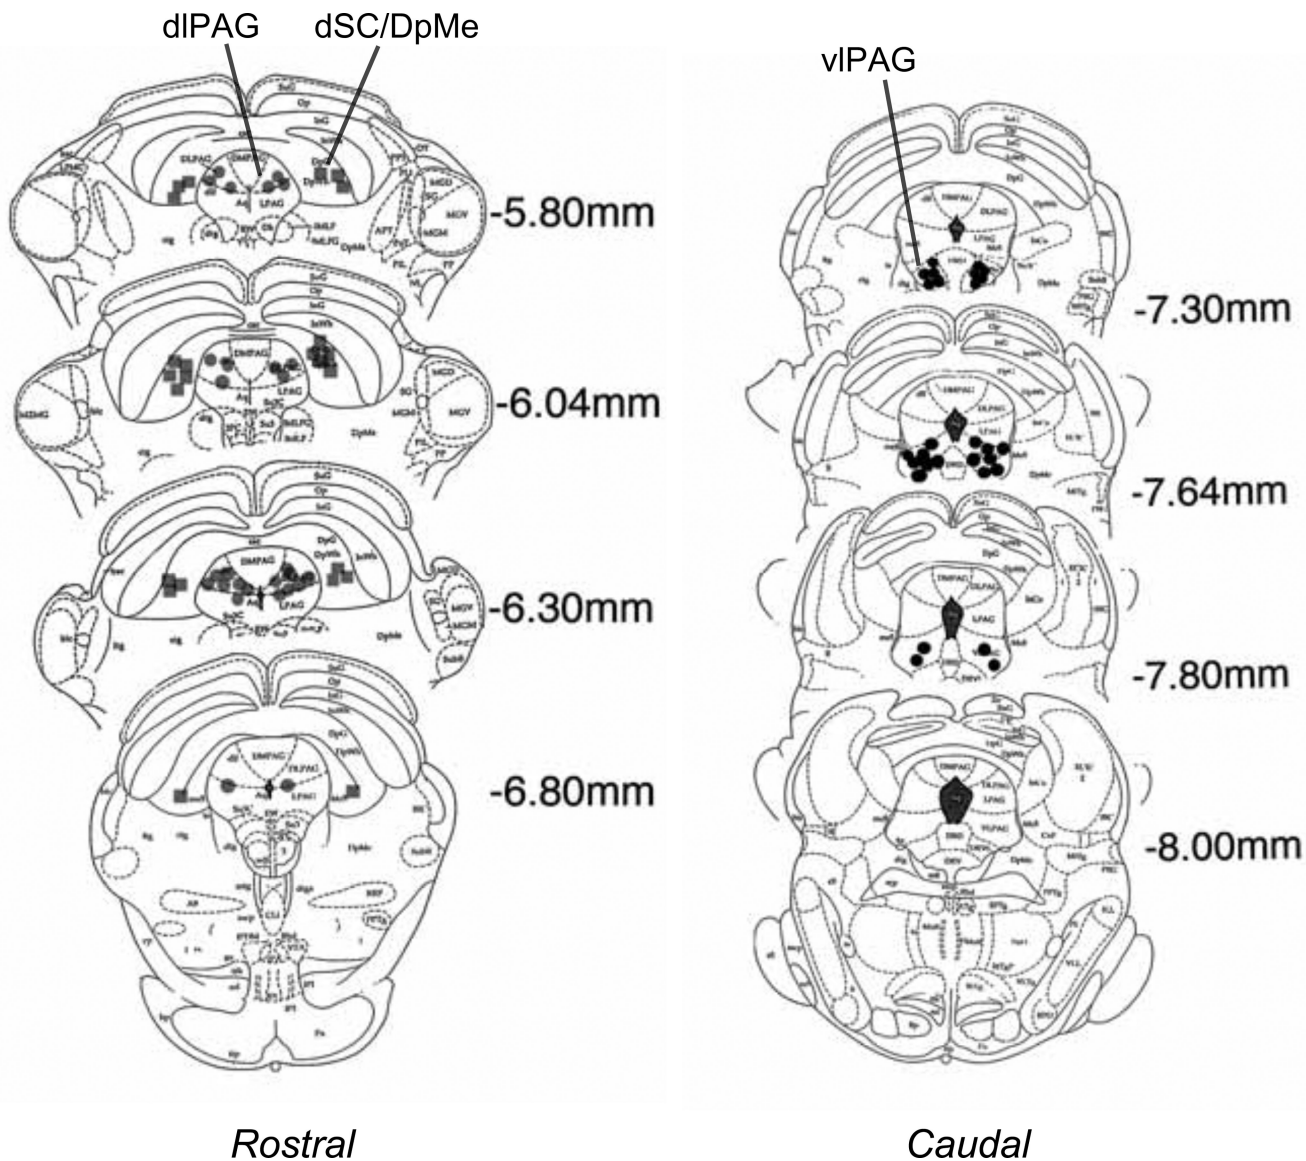

Figure 2. Cannula locations for different rats implanted with cannulas in the dorsal lateral division of the periaqueductal gray (dIPAG); the ventral lateral division of the periaqueductal gray (vIPAG); or the deep layers of the superior colliculus and deep mesencephalic nucleus of the reticular formation (dSC/DpMe). (Plates adapted from Paxinos and Watson, 1997).

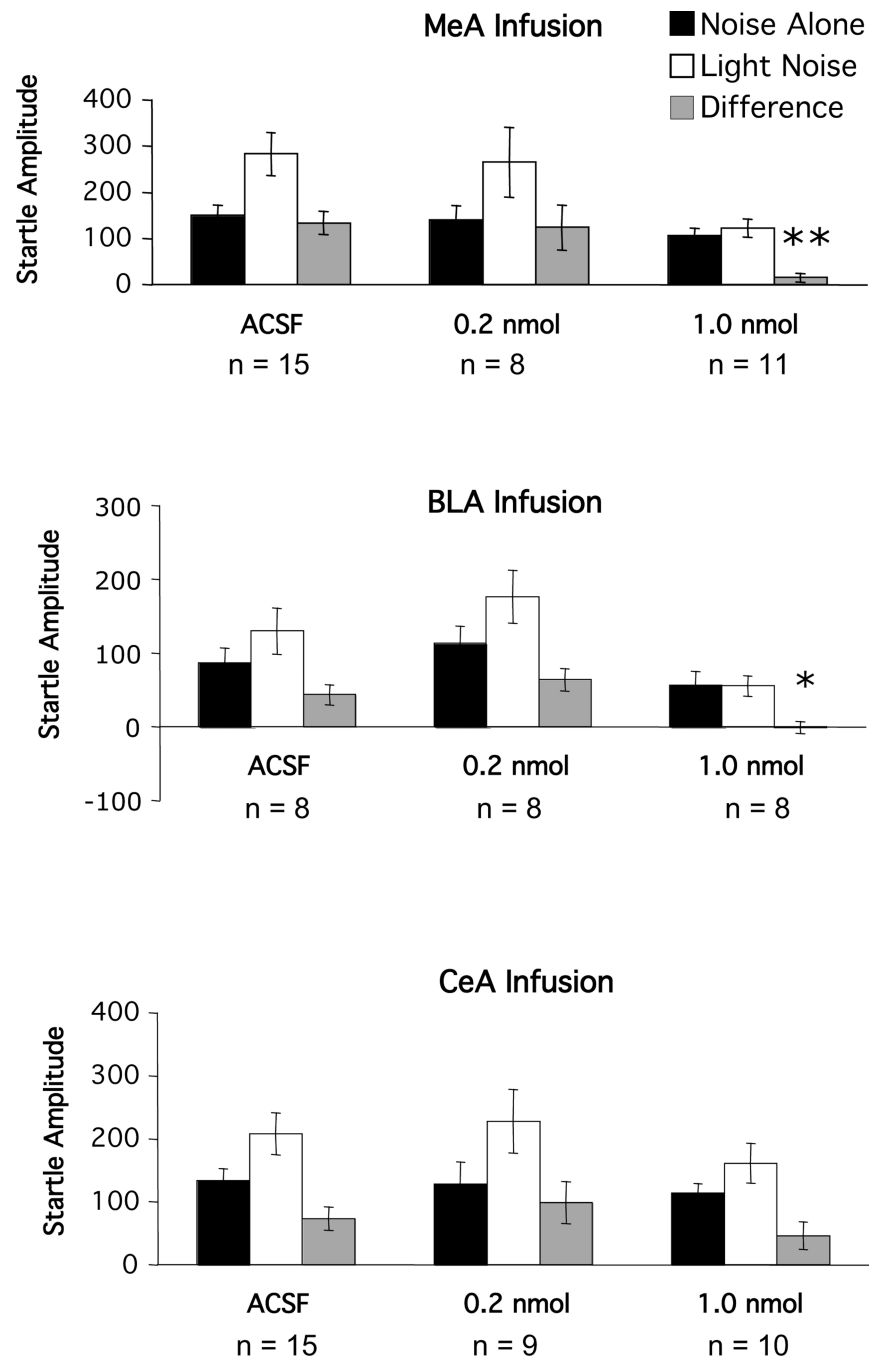

Figure 3. Mean amplitude of the startle reflex in the absence (black bars) or the presence (white bars) of the visual conditioned stimulus, or the difference between these two trial types (gray bars = fear-potentiated startle) after local infusion of various doses of the substance P antagonist GR 82334 into either the medial nucleus of the amygdala (MeA), the basolateral nucleus of the amygdala (BLA) or the central nucleus of the amygdala (CeA).

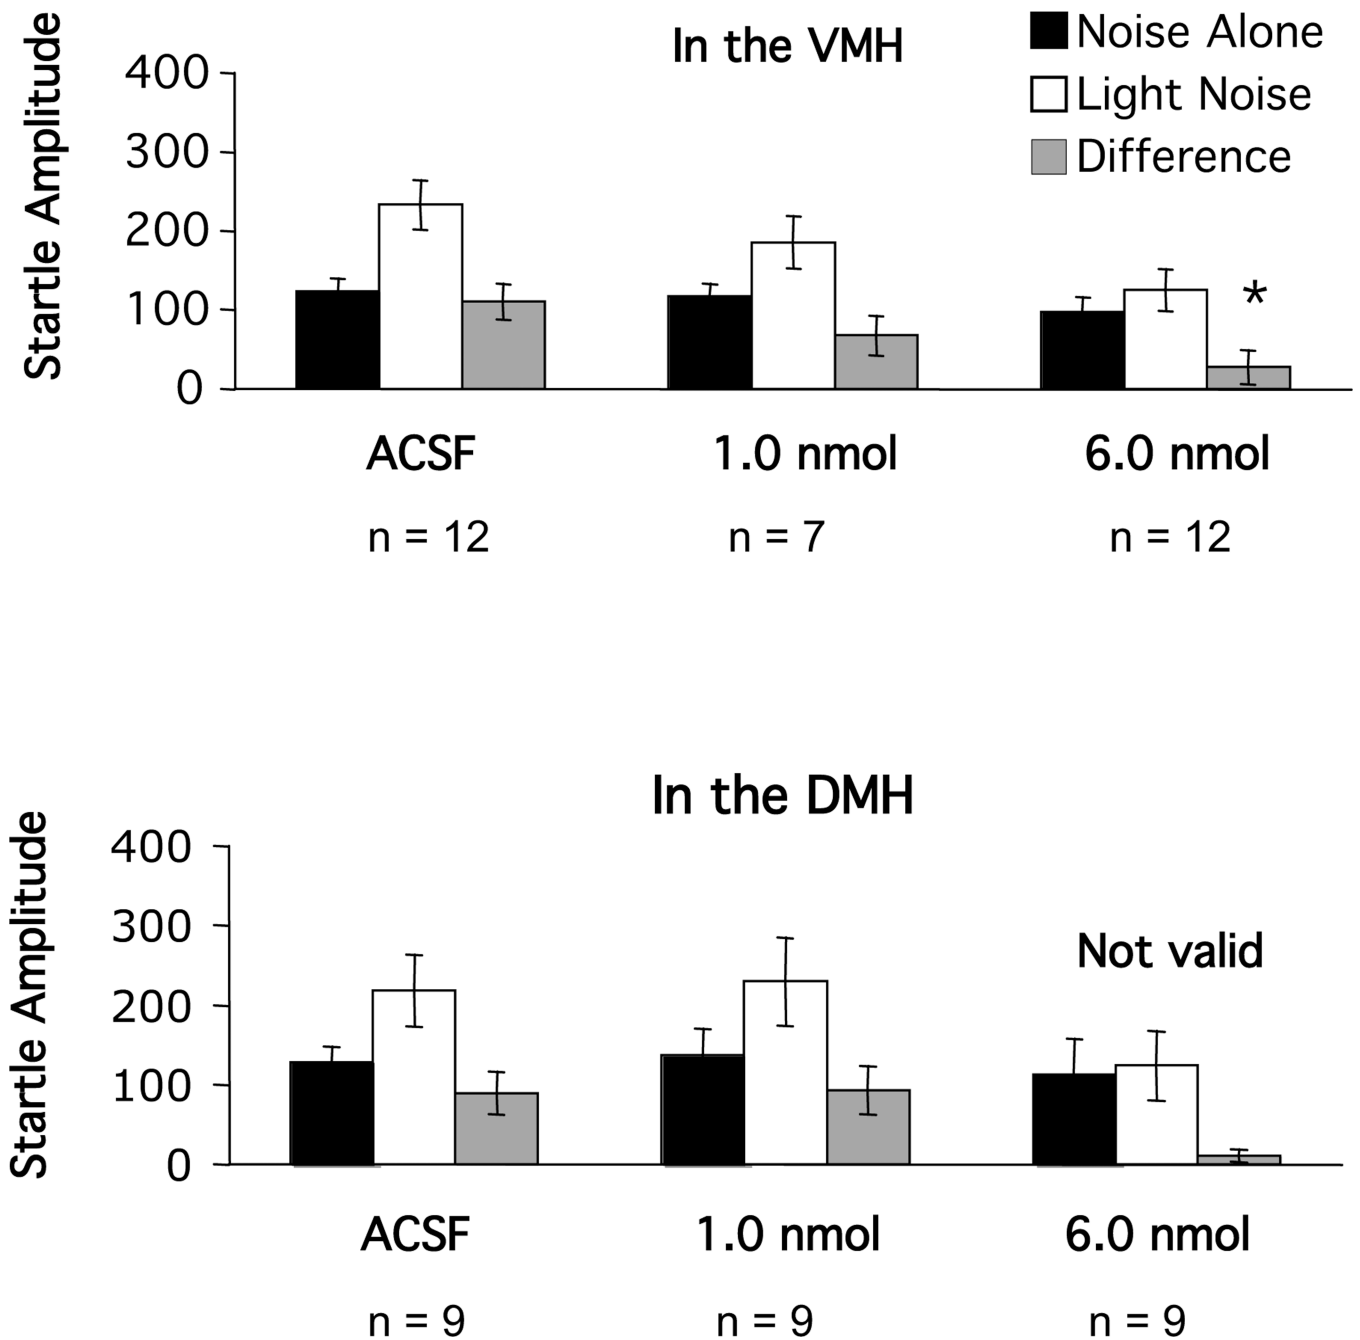

Figure 4. Mean amplitude of the startle reflex in the absence (black bars) or the presence (white bars) of the visual conditioned stimulus, or the difference between these two trial types (gray bars = fear-potentiated startle) after local infusion of various doses of the substance P antagonist GR 82334 into either the ventral (VMH) or dorsal (DMH) nucleus of the hypothalamus.

Figure 5. Mean amplitude of the startle reflex in the absence (black bars) or the presence (white bars) of the visual conditioned stimulus, or the difference between these two trial types (gray bars = fear-potentiated startle) after local infusion of various doses of the substance P antagonist GR 82334 into either rostral part of the dorsal lateral division of the periaqueductal gray (dIPAG); the caudal part of the ventral lateral division of the periaqueductal gray (vIPAG) or the deep layers of the superior colliculus and deep mesencephalic nucleus of the reticular formation (dSC/DpMe).

Figure 6. Mean amplitude of the startle reflex in the absence (black bars) or the presence (white bars) of the visual conditioned stimulus, or the difference between these two trial types (gray bars = fear-potentiated startle) after local infusion of the AMPA receptor antagonist into the rostral part of the dorsal lateral division of the periaqueductal gray (dIPAG), the deep layers of the superior colliculus and deep mesencephalic nucleus of the reticular formation (dSC/DpMe) or after morphine in the caudal part of the ventral lateral division of the periaqueductal gray (vIPAG).

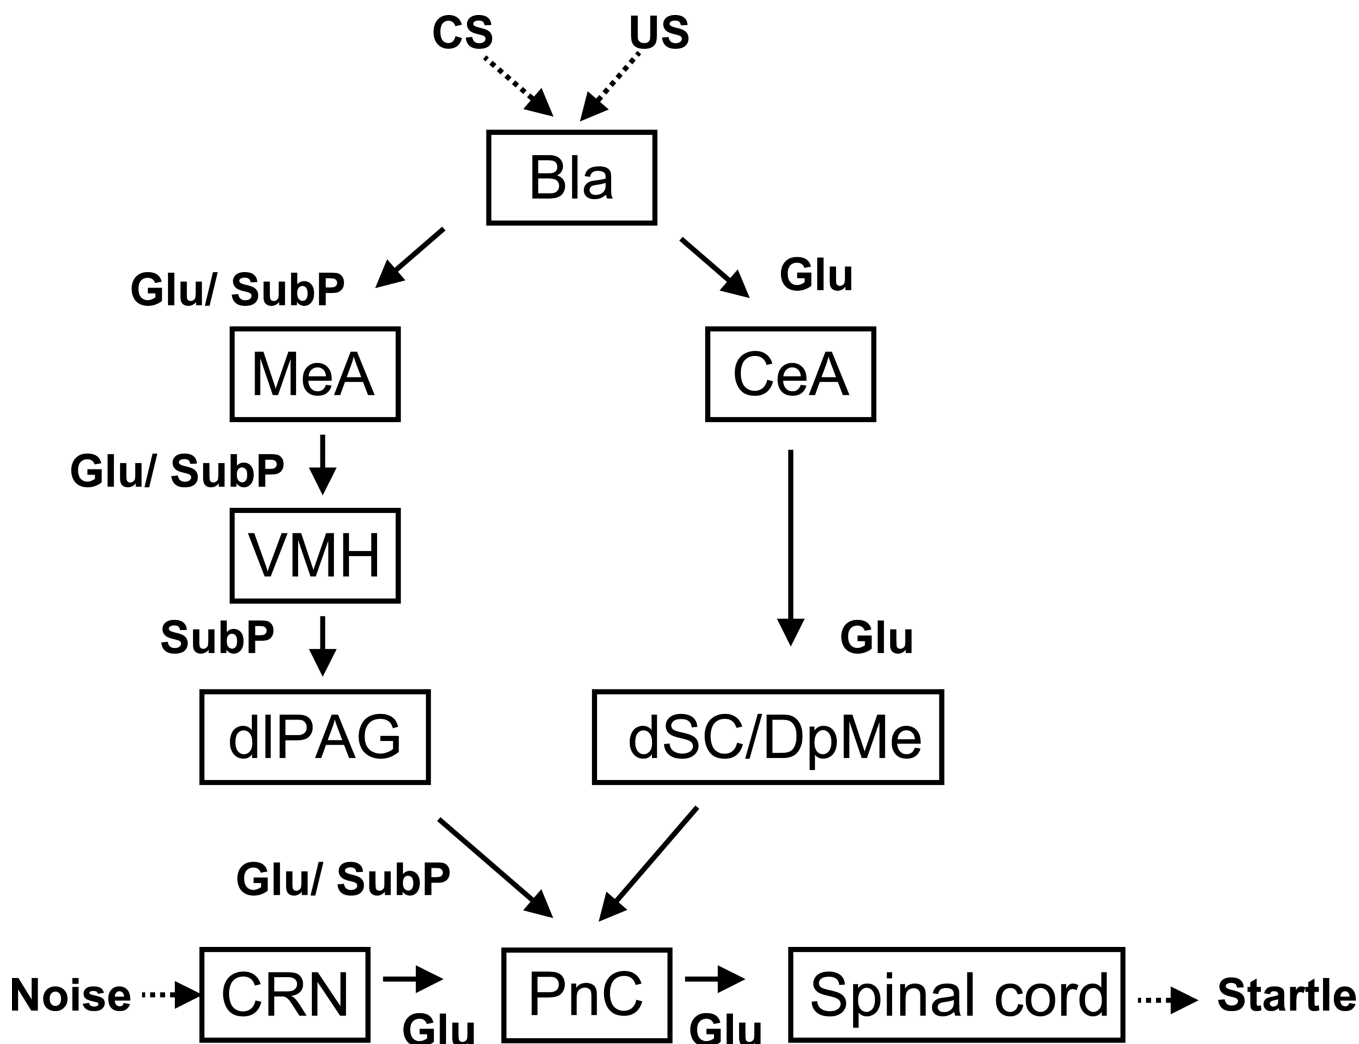

Figure 7. A schematic diagram that illustrates the hypothesized neural pathways through which the amygdala that may mediate fear potentiated startle. Fear is induced by presence of the conditioning stimulus (CS) that was previously paired with the unconditioned stimulus (US), which is indicated by an increase in startle response in presence of the CS. The fear-induced increase in startle is mediated by the amygdala through two separate pathways, namely, the central-amygdalo-tegmento-pontine pathway and the medial-amygdalo-hypothalamo-periaqueducto-pontine pathway. The central-amygdalo-tegmento-pontine pathway involves the central amygdala (CeA), the deep layers of the superior colliculus/deep mesencephalic nucleus (dSC/DpMe) of the midbrain, and the nucleus reticularis pontis caudalis (PnC) of the brainstem. Glutamatergic neurotransmission is required in this pathway. The medial-amygdalo-hypothalamo-periaqueducto-pontine pathway involves the medial nucleus of the amygdala (MeA), the ventromedial nucleus of the hypothalamus (VMH), the dorsolateral periaqueductal gray (dIPAG) of the midbrain and the PnC. In this circuit substance P neurotransmission is required although we do not know how. We hypothesize that it modulates the release of glutamate in some but not all of these nuclei, including the PnC based on the work of . The startle circuit consists of cochlear root neurons (CN) in the auditory nerve, the PnC and the motor neurons in the spinal cord, where noise impinges onto the CN and subsequently elicit rapid startle reflex. The excitability of this circuit can be

elevated by the excitatory inputs from the amygdala to the PnC, thus resulting in increased startle.
