To compare the *in vitro* antibacterial efficacies and resistance profiles of rifampin-based combinations against methicillin-resistant *Staphylococcus aureus* (MRSA) in a biofilm model, the antibacterial activities of vancomycin, teicoplanin, daptomycin, minocycline, linezolid, fusidic acid, fosfomycin, and tigecycline alone or in combination with rifampin against biofilm-embedded MRSA were measured. The rifampin-resistant mutation frequencies were evaluated. Of the rifampin-based combinations, rifampin enhances the antibacterial activities of and even synergizes with fusidic acid, tigecycline, and, to a lesser extent, linezolid, fosfomycin, and minocycline against biofilm-embedded MRSA. Such combinations with weaker rifampin resistance induction activities may provide a therapeutic advantage in MRSA biofilm-related infections.

Methicillin-resistant *Staphylococcus aureus* (MRSA)-associated infections are difficult to cure, and treatment failure or recurrent diseases are common in patients who retain an infected graft. Notably, treatment failure may be related to biofilm formation (1, 2). Rifampin is a component of the active combinations against MRSA and biofilms formed by these organisms (3, 4). However, despite the *in vitro* susceptibility to rifampin of MRSA strains, rapid emergence of rifampin-resistant MRSA isolates, especially biofilm-embedded isolates, has been found (5). Therefore, the use of rifampin monotherapy for MRSA infections is commonly discouraged, and rifampin-based combinations are alternative options for treatment of biofilm-associated MRSA infections. In this study, eight MRSA strains with distinct genotypes identified by pulse-field gel electrophoresis from 33 clinical isolations were used (6, 7). The antimicrobial susceptibility of planktonic or biofilm-embedded MRSA to vancomycin, rifampin, minocycline, fosfomycin, linezolid, tigecycline, fusidic acid, teicoplanin, and daptomycin was tested. All eight isolates were susceptible to all the drugs but minocycline and fusidic acid in common planktonic form. Of note, all isolates had low rifampin MICs (<0.06 $\mu\text{g/ml}$). In general, the minimum biofilm eradication concentrations (MBECs) were higher than the MICs for all isolates (data not shown).

Biofilms of individual strains were prepared in 24-well plates according to a previously described method (8) and were treated with vancomycin, teicoplanin, daptomycin, minocycline, linezolid, fusidic acid, fosfomycin, tigecycline, or rifampin alone or with rifampin-based combinations. The concentrations of most drugs were adjusted to the susceptible breakpoint concentrations (SBCs) recommended by the CLSI (9). The SBCs of fusidic acid and tigecycline were adopted from the British Society for Antimicrobial Chemotherapy (10) and Food and Drug Administration (11) guidelines. Specifically, the following concentrations were used: for vancomycin, 2 $\mu\text{g/ml}$; for teicoplanin, 8 $\mu\text{g/ml}$; for daptomycin, 1 $\mu\text{g/ml}$; for minocycline, 4 $\mu\text{g/ml}$; for linezolid, 4 $\mu\text{g/ml}$; for fusidic acid, 1 $\mu\text{g/ml}$; for fosfomycin, 64 $\mu\text{g/ml}$; for tigecy-

cline, 0.5 $\mu\text{g/ml}$; and for rifampin, 1 $\mu\text{g/ml}$. The drug-containing medium was gently aspirated after 1 day at 37°C, and the biofilm on the wells was incubated with fresh drug dilutions for 5 consecutive days, followed by counting at day 5. The bacterial loads determined for the rifampin-based combinations were compared to those seen with monotherapy. The presence of synergism was defined as a ≥ 100 -fold reduction of the bacterial load after treatment with a combination regimen versus the load determined after treatment with the more active drug in the combination. The inhibition effects of each drug alone and in combination with rifampin are shown in Fig. 1 and Table 1.

Rifampin alone showed a poor inhibitory effect, despite low MICs for MRSA. In contrast, linezolid alone exhibited a potent inhibitory effect, namely, a 3.68 to 4.92 \log_{10} reduction of bacterial load. Fosfomycin alone also produced a 2.79 to 5.34 \log_{10} reduction against all but one resistant isolate (no. 3562). Synergism was noted in the combinations rifampin plus linezolid (four MRSA isolates), rifampin plus fosfomycin (four), rifampin plus minocycline (five), rifampin plus fusidic acid (eight), and rifampin plus tigecycline (eight).

To study the emergence of rifampin-resistant mutants from biofilm-embedded MRSA isolates incubated with rifampin alone or in combination with other agents, surviving colonies were collected and the highest MICs of rifampin were evaluated. Rifampin-resistant isolates (those with the highest MIC > 64 $\mu\text{g/ml}$) emerged readily in the eight MRSA isolates incubated with SBCs

FIG 1 Bacterial load reduction (\log_{10} CFU/ml) of eight methicillin-resistant *Staphylococcus aureus* strains in biofilm after exposure to nine antibiotics alone or in combination with rifampin for 5 days at the following susceptible breakpoint concentrations: vancomycin (VA) 2 $\mu\text{g/ml}$, teicoplanin (TEC) 8 $\mu\text{g/ml}$, daptomycin (DAP) 1 $\mu\text{g/ml}$, minocycline (MNO) 4 $\mu\text{g/ml}$, linezolid (LNZ) 4 $\mu\text{g/ml}$, fusidic acid (FA) 1 $\mu\text{g/ml}$, fosfomycin (FOS) 64 $\mu\text{g/ml}$, tigecycline (TGC) 0.5 $\mu\text{g/ml}$, and rifampin (RIF) 1 $\mu\text{g/ml}$. The black bar represents the single antibiotic, and the white bar represents the rifampin base combination with the left antibiotic.

of rifampin alone or in combination with vancomycin, teicoplanin, or daptomycin (Table 2). In contrast, the rifampin MICs of the surviving colonies from eight MRSA isolates treated with the combinations of rifampin plus linezolid, rifampin plus fusidic acid, rifampin plus fosfomycin, or rifampin plus tigecycline were not higher than 0.06 $\mu\text{g/ml}$. For the combination of rifampin and minocycline, the MIC results were divergent. Among five MRSA isolates in which rifampin plus minocycline showed synergistic antibacterial activity, rifampin-resistant isolates (>64 $\mu\text{g/ml}$)

could not be found, but they were easily found among the MRSA isolates without rifampin-minocycline synergism.

In order to understand how many survival strains of biofilm-embedded MRSA have higher rifampin MICs after antibiotic treatment, resistant strains from surviving colonies were further plated with or without 0.06 or 64 $\mu\text{g/ml}$ rifampin to measure the mutation and high-level-resistance rates. The mutation and high-level-resistance rates were 104.2% and 103.2% for rifampin alone, 100.5% and 103.6% for rifampin plus vancomycin, 105.0% and 104.5% for rifampin plus teicoplanin, 98.6% and 99.1% for rifampin plus daptomycin, and 101.5% and 100.6% for the nonsynergistic rifampin-plus-minocycline combination. In contrast, the mutation and high-level-resistance rates were 0% and 0% for the combinations of rifampin plus linezolid, rifampin plus fusidic acid, rifampin plus fosfomycin, rifampin plus tigecycline, and synergistic rifampin plus minocycline. Nearly all surviving bacteria from the plates treated with rifampin alone or in combination with vancomycin, teicoplanin, daptomycin, or minocycline were highly resistant to rifampin, with MICs > 64 $\mu\text{g/ml}$ (Fig. 2).

In the present study, the rifampin combinations with fusidic acid, tigecycline, and, to a lesser extent, linezolid, minocycline, and fosfomycin exhibited synergistic activity against eight MRSA isolates. Linezolid monotherapy, as we previously reported (8), exhibited excellent inhibitory effects against biofilm-embedded MRSA. Rifampin augmented the antibacterial effect of linezolid in biofilm, as we previously found (8, 12). Vancomycin plus rifampin has exhibited an *in vitro* synergistic effect against MRSA isolates with a high vancomycin MIC (2 $\mu\text{g/ml}$) (13). However, the emergence and spread of rifampin-resistant MRSA isolates during vancomycin-rifampin combination therapy in an intensive care unit has been reported (14). Such a combination could easily induce high-level rifampin resistance (MIC > 64 $\mu\text{g/ml}$) in biofilm-embedded MRSA isolates, according to our *in vitro* study (8).

Although tigecycline has been considered for treatment of bio-

film-embedded MRSA infection (5), our results question the therapeutic value of tigecycline monotherapy. However, at the susceptible breakpoint concentrations used in our experiments, which are feasible and compatible with achievable serum levels with currently recommended dosages, rifampin plus tigecycline could have synergistic antibacterial activity against MRSA in biofilm, with rare rifampin-resistant mutants. On the other hand, the combination of minocycline and rifampin, as used in our previous study (12), possesses a synergistic effect and leads to fewer mutants in MRSA in biofilm. That combination has not been mentioned before.

In vitro, daptomycin is considered effective and the fastest in eradicating MRSA in biofilm (5). However, *in vivo* studies have reported different results. Miró et al. found that the addition of gentamicin or rifampin did not enhance the effectiveness of daptomycin in the treatment of experimental endocarditis due to MRSA (15). Furthermore, our study found a poor effect of daptomycin monotherapy, and even of daptomycin combined with rifampin, against MRSA in biofilm. Certainly, rifampin-resistant

mutants, especially isolates with high-level resistance, could easily be selected during such combination therapy. Such diversity might also be related to the concentrations used during the experiments, as we previously mentioned (8).

The combination of fusidic acid and rifampin is effective against MRSA infections (4, 16–18). Occasionally, such a combination can be a treatment option for heterogeneous vancomycin-intermediate *S. aureus* (hVISA) or VISA infections (19), as supported by our finding that fusidic acid plus rifampin is effective in decreasing bacterial loads in the biofilm model. In addition, the frequency of rifampin-resistant mutations in the presence of fusidic acid and rifampin in *S. aureus* is lower than that seen with rifampin monotherapy (10^{-11} versus $<10^{-8}$) (20). Therefore, the rifampin-fusidic acid combination with synergism and low rifampin mutation-inducing activity could be useful as a long-term maintenance therapy for biofilm-associated MRSA infections.

Fosfomycin has long been used in combination therapies against MRSA, especially in biofilm (8, 13). When used in a combination against biofilm-embedded MRSA, it possesses less mutation-inducing potential than rifampin (8). However, the combination of fosfomycin with rifampin, which had never been used before, seemed to enhance the inhibitory activity and even synergism when used against some of the tested MRSA isolates. More evidence is needed to determine whether this combination also has low rifampin mutation-inducing activity.

In conclusion, we found that rifampin enhances the antibacterial activities of and even synergizes with fusidic acid, tigecycline, and, to a lesser extent, linezolid, fosfomycin, and (in part) minocycline against biofilm-embedded MRSA. Such combinations also possess weaker rifampin resistance induction activities. Animal experiments and clinical studies are essential to validate the usefulness of these rifampin-based combination regimens in clinical management of biofilm-related MRSA infections.
