ABSTRACT

INTRODUCTION: Atypical presentations of appendix have been reported including backache, left lower quadrant pain and groin pain from a strangulated femoral hernia containing the appendix. We report a case presenting an epigastric pain that was diagnosed after computed tomography as a perforated appendicitis on intestinal malrotation.

PRESENTATION OF CASE: A 27-year-old man was admitted with a three-day history of epigastric pain. Physical examination revealed tenderness and defense on palpation of epigastric region. There was a left subcostal incision with the history of diaphragmatic hernia repair when the patient was 3 days old. He had an intestinal malrotation with the cecum fixed at the epigastric region and the inflamed appendix extending beside the left lobe of liver.

DISCUSSION: While appendicitis is the most common abdominal disease requiring surgical intervention seen in the emergency room setting, intestinal malrotation is relatively uncommon. When patients with asymptomatic undiagnosed gastrointestinal malrotation clinically present with abdominal pain, accurate diagnosis and definitive therapy may be delayed, possibly increasing the risk of morbidity and mortality.

CONCLUSION: Atypical presentations of acute appendicitis should be kept in mind in patients with abdominal pain in emergency room especially in patients with previous childhood operation for diaphragmatic hernia.

1. Introduction

Appendicitis is the most frequent surgical emergency that requires removal of the appendix. Typical symptoms are periumbilical pain radiating to right lower quadrant with peritoneal irritation on abdominal examination, anorexia and fever. Atypical presentations have been reported including backache,¹ left lower quadrant pain² and groin pain from a strangulated femoral hernia containing the appendix.³

We report a case presenting an epigastric pain that was diagnosed after computed tomography (CT) as a perforated appendicitis on intestinal malrotation.

2. Presentation of case

A 27-year-old man was admitted to the Haydarpasa Numune Education and Research Hospital, Emergency Department,

Istanbul. He had a three-day history of epigastric pain. The pain was associated with nausea, vomiting, anorexia and high fever.

Physical examination revealed tenderness and defense on palpation of epigastric region. There was a left subcostal incision with the history of diaphragmatic hernia repair when the patient was 3 days old. A laboratory examination revealed an elevated white blood cell (WBC) count at 19,800/ μ L with 76, 6% neutrophils (absolute neutrophil count: 15,200). Biochemical tests and urinalysis were normal.

Abdominal plain films demonstrated colonic air at epigastric region and left upper quadrant. Intestinal malrotation was not considered in the differential diagnosis at that point. No pneumoperitoneum was evident (Fig. 1). With a wide range of differential diagnosis (acute cholecystitis, perforated ulcer, pancreatitis, etc.), the patient had undergone an abdominal ultrasound that was unable to justify his symptoms. There was only minimal fluid in Morison's pouch. Therefore, he had an abdominal CT scan the next day with IV contrast. He had an intestinal malrotation with the cecum fixed at the epigastric region and the inflamed appendix extending beside the left lobe of liver. Patient had a partial situs viscerus inversus. Liver was located at original place, but stomach, spleen and pancreas were at right side of the abdomen under liver (Fig. 2A and B).

The patient was transferred to the emergency operating room for laparoscopic appendectomy. After scrubbing, we did a vertical

incision 5 cm above the umbilicus and insufflation of the abdominal cavity, we explored the abdomen with a 0° optic. We used the supraumbilical optic tractor because we knew that appendix was located in the epigastric region according to CT findings. Another two 5 mm trocars were inserted to the left and the right sides 10 cm above the umbilicus at midclavicular lines. We first noticed the inflamed bowel segment lateral to the left lobe of liver. Appendectomy was performed and the inflamed appendix was extracted in an endobag and was sent to pathology (Figs. 3 and 4). Because of perforated appendix, necrosis and pus at appendectomy site, an intraabdominal drain was placed to prevent abscess formation.

The postoperative course was unremarkable and the drain in the epigastric region could be removed on post op day 5. The patient was discharged 6 days later without any complications.

Pathology report mentioned perforated gangrenous appendicitis with an acute periappendicular abscess.

3. Discussion

While appendicitis is the most common abdominal disease requiring surgical intervention seen in the emergency room setting, intestinal malrotation is relatively uncommon.⁴ Intestinal malrotation represents the errors of rotation of the midgut about the superior mesenteric artery during weeks 5–10 of fetal life and subsequent abnormal fixation to the peritoneal wall. The estimated incidence of intestinal malrotation is 1 in every 500 live births⁵ based on autopsy series, retrospective reviews,⁶ and prospective barium enema studies.⁷ The true incidence of adults with asymptomatic malrotation remains difficult to accurately determine.

The typical history of appendicitis includes pain starting perumbilically before localizing to the right iliac fossa; this is due to the poor localizing property of visceral nerves from the mid-gut, followed by the involvement of somatic nerves (parietal peritoneum) as the inflammation progresses. The pain is usually associated with loss of appetite and fever. Nausea or vomiting may or may not

occur.² However, in our case the pain was located in the epigastric region and no pain was noted in the right abdomen. Although atypical locations are frequently seen,^{1–3} epigastric localization of acute appendicitis was not reported in the literature.

When patients with asymptomatic undiagnosed gastrointestinal malrotation clinically present with abdominal pain, accurate diagnosis and definitive therapy may be delayed, possibly increasing the risk of morbidity and mortality.^{4,8}

Other cases of appendicitis in adults or adolescents in the context of intestinal malrotation have been described previously,^{5–7,9–12} frequently with delayed or incorrect initial diagnoses. Several of these prior reports describe the diagnosis of acute appendicitis and gastrointestinal malrotation based on abdominal CT, further immediate dynamic imaging of the intestinal malrotation is often unnecessary, provided the CT is sufficient for surgical planning, as in this case. Furthermore, the sensitivity and specificity of upper gastrointestinal, fluoroscopic barium enema or abdominal ultrasound in adolescent or adult patients for detection of causes of an acute abdomen are limited compared to CT.

In our case, abdominal ultrasonography made the diagnosis of acute appendicitis less likely. However, the persistence of pain and the increasing inflammatory parameters in his blood exams pushed the medical team to further investigate and a CT scan revealed intestinal malrotation with acute appendicitis.

In a study, including 331 cases of intestinal rotation, there were 111 (33, 5%) neonates with malrotation caused by diaphragmatic hernia.¹³ Our patient had an operation for diaphragmatic hernia when he was 3 days old. Therefore, we should keep in mind the association of diaphragmatic hernia and possibility of intestinal malrotation.

4. Conclusion

Atypical presentations of acute appendicitis should be kept in mind in patients with abdominal pain in emergency room

especially in patients with previous childhood operation for diaphragmatic hernia. CT scan is superior to ultrasonography in the diagnosis of atypical localization of the appendix.
