Abstract

Objective—To compare the effect initiating different antiretroviral therapy (ART) regimens have on weight, body mass index (BMI), and lean body mass (LBM) and explore how changes in body composition are associated with bone mineral density (BMD).

Methods—A5224s was a substudy of A5202, a prospective trial of 1857 ART-naïve participants randomized to blinded abacavir-lamivudine (ABC/3TC) or tenofovir DF-emtricitabine (TDF/FTC) with open-label efavirenz (EFV) or atazanavir-ritonavir (ATV/r). All subjects underwent dual-energy absorptiometry (DXA) and abdominal CT for body composition. Analyses used 2-sample t-tests and linear regression.

Results—A5224s included 269 subjects: 85% male, 47% white non-Hispanic, median age 38 years, HIV-1 RNA 4.6 $\log_{10}$ copies/mL, and CD4 233 cells/μL. Overall, significant gains occurred in weight, BMI, and LBM at 96 weeks post randomization (all p<0.001). Assignment to ATV/r (vs EFV) resulted in significantly greater weight (mean difference 3.35 kg) and BMI gain (0.88 kg/m^2; both p=0.02), but not LBM (0.67 kg; p=0.15), while ABC/3TC and TDF/FTC were not significantly different (p 0.10). In multivariable analysis, only lower baseline CD4 count and higher HIV-1 RNA were associated with greater increase in weight, BMI, or LBM. In multivariable analyses, increased LBM was associated with an increased hip BMD.

Conclusions—ABC/3TC vs. TDF/FTC did not differ in change in weight, BMI, or LBM; ATV/r vs. EFV resulted in greater weight and BMI gain but not LBM. A positive association between

increased LBM and increased hip BMD should be further investigated through prospective interventional studies to verify the impact of increased LBM on hip BMD.

antiretroviral therapy; HIV; body composition; body weight; lean body mass; bone mineral density; randomized clinical trial

INTRODUCTION

Body weight is considered a key determinant of bone mineral density, however the body weight component among lean mass, peripheral fat mass or visceral adipose tissue with the greatest impact on bone mass is debated [1, 2]. Lean body mass augments bone mineral density through mechanical load forces and lean body mass is associated with lower risk of bone fractures [3, 4]. Fat mass can have a positive interaction on bone through skeletal loading and adipocyte hormone production, but inflammatory cytokines produced in visceral adipose tissue may exacerbate bone loss [5]. Furthermore, the impact of total fat mass and total lean body mass on bone mineral density may differ by age, sex, race, and skeletal site [6].

Low bone mineral density is reported across multiple cohorts of both men and women with HIV-infection, with a strong association between lower baseline weight and both lower baseline bone mineral density [7, 8] and a greater decline in bone mineral density with antiretroviral therapy (ART) initiation [9–11]. Prior to initiating antiretroviral therapy, individuals with HIV infection have lower bone mineral density than the general population [12]. Lower weight appears to mediate a significant proportion of the bone mineral density differences [13]. The initiation of antiretroviral therapy is often characterized by weight gain [14–17], and it is hypothesized that these changes in weight help to stabilize bone mineral density after the initial loss in bone mineral density observed with ART initiation [13]. Changes in central and peripheral fat with ART initiation and ART regimens are also well-described, however a gain in adiposity could be associated with a myriad of other health problems [18–20]. Despite a strong association between greater muscularity and lower mortality [21, 22], comparisons of the role of individual ART on lean body mass and the contribution of body composition components on bone mineral density have not been well defined.

We have previously presented data on changes after ART initiation in bone mineral density, peripheral fat, and visceral adipose tissue from AIDS Clinical Trials Group A5224s, a substudy of A5202, in which HIV-infected treatment-naïve participants were randomized in a double-blinded fashion to abacavir/lamivudine (ABC/3TC) or tenofovir DF/emtricitabine (TDF/FTC) with open-label efavirenz (EFV) or atazanavir-ritonavir (ATV/r) [20, 23]. Briefly, randomization to TDF/FTC led to a greater decrease in spine and hip bone mineral density, less gain in limb fat, and no significant difference in change in visceral fat compared to ABC/3TC [20, 23]. Assignment to ATV/r led to greater losses in spine but not hip bone mineral density, and was associated with significantly greater increase in limb fat and a trend towards greater increase in visceral fat compared to EFV. Here we compare the changes in weight, body mass index (BMI), and lean body mass between the nucleoside reverse transcriptase inhibitor (NRTI) components and the non-nucleoside reverse transcriptase inhibitor/protease inhibitor (NNRTI/PI) components from A5224s. We also explore the association of changes in BMI, lean body mass, and fat mass with changes in bone mineral density.

METHODS

A5224s was a sub-study of AIDS Clinical Trials Group A5202, in which ART-naïve persons aged 16 years and with an HIV-1 RNA load >1000 copies/mL received TDF/FTC or ABC/3TC, with EFV or ATV/r at standard doses. The primary analyses of both A5202 and A5224s have been presented previously [20, 23–26]. Specific A5224s exclusion criteria were uncontrolled thyroid disease or hypogonadism; endocrine diseases, including Cushing's syndrome, diabetes mellitus, and the use of growth hormone, anabolic steroids, glucocorticoids, or osteoporosis medications (calcium and/or vitamin D were not included); or the intent to start these treatments known to influence bone mineral density. The duration of the study was 96 weeks after the last A5202 participant enrolled.

Any participant enrolling in A5202 at one of the AIDS Clinical Trials Group sites participating in A5224s and meeting criteria for A5224s was eligible to enroll in the sub-study; A5202 randomization was stratified by willingness to enroll into the substudy. Each participant signed a written informed consent before enrollment. The study was approved by the local institutional review board at each site.

At baseline, a complete history was obtained and participants underwent a physical examination, including standardized measurement of height and weight. Substudy evaluations, regardless of antiretroviral treatment status, included whole-body dual-energy absorptiometry (DXA) and site-specific (hip and lumbar spine) bone DXA at baseline and at weeks 24, 48, 96, and every 48 weeks until the end of follow-up, as well as a single-slice abdomen CT scan at the L4–L5 level at baseline and week 96. lean body mass was defined as fat-free, bone-free mass as measured by DXA in the anteroposterior view (using Hologic or Lunar scanners). Hip bone mineral density, lumbar spine bone mineral density (from L1-L4), and limb fat were measured by DXA. Technicians were instructed to scan the same hip of each participant for all bone mineral density measurements and to use the same DXA machine on the same participant throughout the study. CT was used to quantify visceral adipose tissue. All DXAs and CT scans were standardized at the participating sites, then centrally read (Tufts) by blinded personnel.

On 18 February 2008, after a median follow-up of 97 weeks (range 0–124 weeks; Q1–Q3 58–108 weeks), the Data Safety and Monitoring Board recommended unblinding the NRTI component of the study for subjects with screening HIV-1 RNA levels 100,000 copies/mL because of excess virological failures associated with ABC/3TC; subjects receiving ABC/3TC were permitted to modify their NRTI regimen [24].

Statistical Analysis

The current study was a post-hoc, exploratory analysis to compare changes from baseline to week 96 in weight, BMI, and lean body mass between pooled, randomized NRTI components (ABC/3TC versus TDF/FTC) and NNRTI/PI components (ATV/r versus EFV). All analyses were initially performed using the intent-to-treat principle based on randomized treatment assignment in which all available data were included and modifications to randomized treatment were ignored; no imputations were made for missing values. Supplemental as-treated analyses were performed in which values were censored after a change in the randomized NRTI component (when comparing NRTI components) or NNRTI/PI component (when comparing NNRTI/PI components). Comparisons used a factorial analysis approach in which, after assessing for treatment effect modification by the other component, the NRTI effect was analyzed by combining EFV and ATV/r arms and vice versa. The assessment of treatment effect modification (interaction) of each ART component with screening HIV-1 RNA stratum (<100,000 or 100,000 copies/mL) was pre-specified.

Changes from baseline within study arm or regimen component used 1-sample t-tests. Comparisons between regimen components used 2-sample t-tests. There was no evidence of an interaction between the NRTI and NNRTI/PI components on 96 week change in weight, BMI, or lean body mass (all p 0.30). Analyses that adjusted for baseline and post-baseline factors and explored associations with baseline and post-baseline factors used linear regression; all multivariable models were adjusted for both ART components. Univariate associations with a p-value <0.20 were included in a multivariable model which utilized backwards selection and only factors with a p-value <0.05 were retained. Analyses were performed using SAS, version 9.1.3 (SAS Institute).

RESULTS

Participant Characteristics

A total of 271 participants from 37 AIDS Clinical Trials Group sites in the United States and Puerto Rico were randomized to receive ART; 2 participants were excluded from the analysis for eligibility violations. Sixty-nine participants were randomized to receive EFV plus TDF/FTC, 70 to EFV plus ABC/3TC, 65 to ATV/r plus TDF/FTC, and 65 to ATV/r plus ABC/3TC. Baseline characteristics are summarized in Table 1 and were balanced across study arms. The median age of the subjects was 38 years, 85% were male, and 47% were white non-Hispanics. The mean weight was 78.0 kg, BMI was 24.9 kg/m^2, CD4 cell count was 233 cells/μL, plasma HIV-1 RNA was 4.6 log$_{10}$ copies/mL, and 80% had an HIV-1 RNA <100,000 copies/mL at study entry.

Sixty-six (25%) of A5224s participants prematurely discontinued study follow-up, 4 (1%) died, and 45% modified the randomized treatment regimen. These details have been previously published [20, 23].

Change in Weight

Among all participants, weight increased from baseline by a mean of 4.8 kg at week 96 (p<0.001). The mean changes in weight for each study arm are shown in Figure 1A. Although ABC/3TC had a trend towards greater weight gain compared to TDF/FTC by intent-to-treat analyses at week 96, this difference was not statistically significant (Figure 1A). Results in the as-treated analysis were similar (Δ=2.00 kg; 95% CI −0.94, 5.06 kg; p=0.21). ATV/r assignment resulted in significantly greater weight gain in both intent-to-treat (Figure 1A) and as-treated analyses (Δ=3.24 kg; 95% CI 0.13, 6.36 kg; p=0.04) compared to EFV.

Change in BMI

Among all participants, BMI increased by a mean of 1.5 kg/m^2 at week 96 (p<0.001). The mean changes in BMI across study arms are shown in Figure 1B. No significant differences in BMI were detected between ABC/3TC and TDF/FTC by intent-to-treat (Figure 1B) or as-treated analyses (Δ=0.53 kg/m^2; 95% CI −0.25, 1.31 kg/m^2; p=0.18). Participants randomized to ATV/r experienced a 0.88 kg/m^2 greater increase in BMI compared to EFV in the intent-to-treat analysis (Figure 1B). BMI increase was also higher in the ATV/r compared to EFV by as-treated analysis (Δ=0.90; 95% CI 0.10, 1.70 kg/m^2; p=0.028).

Change in Lean Body Mass

Across all treatment arms, lean body mass increased significantly by a mean 1.4 kg at week 96 (p<0.001). Mean changes in lean body mass across study arms are shown in Figure 1C. No significant differences in lean body mass gain were seen between ABC/3TC and TDF/FTC by intent-to-treat (Figure 1C) or as-treated analyses (Δ=−0.03 kg; 95% CI −1.09, 1.03 kg; p=0.96). In comparison to those receiving EFV, participants randomized to ATV/r did

not have a significantly different lean body mass change by intent-to-treat analysis (Figure 1C) but the difference did approach statistical significance by as-treated analysis (Δ=1.03 kg; 95% CI −0.01, 2.07 kg; p=0.051).

A pre-specified intent-to-treat subgroup analysis detected a significant interaction between the NNRTI/PI component and screening HIV-1 RNA stratum (p=0.053), indicating that the treatment effect differed by RNA level. Participants with screening HIV-1 RNA 100,000 copies/mL had a significantly greater mean gain in lean body mass with ATV/r (n=38) compared to EFV (n=43; Δ=1.75 kg; 95% CI 0.18, 3.33; p=0.029). Differences between ATV/r (n=56) and EFV (n=66) in lean body mass gain were not seen among participants with HIV-1 RNA <100,000 copies/mL (Δ=−0.06 kg; 95% CI −1.15, 1.03 kg; p=0.91).

Baseline Associations with Change in Total Body Mass, BMI, and Lean Body Mass

In both univariate and multivariable analyses of variables associated with body composition change, higher baseline HIV-1 RNA level and lower CD4 count were associated with a greater gain in total body mass, BMI, and lean body mass at week 96 after adjusting for treatment arm (Table 2).

Multivariable Linear Regression Analyses

Univariate and multivariable analyses assessed baseline and post-baseline factors associations with week 96 change in hip and lumbar spine bone mineral density. Compared to TDF/FTC, assignment to ABC/3TC was associated with less percent loss in hip bone mineral density from week 0 to week 96 (mean Δ 1.35; 95% CI 0.18, 2.53; p=0.02; results previously presented [23]). The change in hip bone mineral density between ATV/r and EFV arms was not statistically significant (mean Δ −0.31; 95% CI −1.50, 0.89; p=0.61). For hip bone mineral density, in addition to the significant TDF/FTC effect, lower baseline weight, higher increase in CD4 count over 96 weeks, lesser increase in lean body mass at 96 weeks, and history of fracture were independently and significantly associated with less increase in hip bone mineral density at 96 weeks after adjusting for treatment arm.

Compared to TDF/FTC, assignment to ABC/3TC was associated with less percent loss in lumbar spine bone mineral density from week 0 to 96 (mean Δ 2.00; 95% CI 0.66, 3.33; p=0.004) while ATV/r was associated with significantly greater percent loss in lumbar spine bone mineral density compared to EFV (mean Δ −1.46; −2.82, −0.10; p=0.035; results previously presented [23]). In multivariable analyses, higher baseline HIV-1 RNA, lower baseline CD4 count, and lack of HIV-1 RNA suppression <50 copies/mL at week 96 were independently and significantly associated with a less increase in lumbar spine bone mineral density at 96 weeks after adjusting for treatment arm (Table 3).

DISCUSSION

Our study presents the first longitudinal assessment of changes in lean body mass after the initiation of antiretroviral therapy and the first longitudinal assessment of body fat, visceral fat, and lean body mass on the change on bone density with current first-line antiretroviral therapy initiation. In the setting of a large, randomized trial of antiretroviral initiation among treatment-naïve subjects, we demonstrated an increase in body weight and BMI across all treatment arms, consistent with prior studies [14–16, 18]. A significantly greater gain in total body mass and BMI was observed in the ATV/r arm compared to the EFV arm. Lower baseline CD4 count and higher HIV-1 RNA had a strong association with a positive gain in total body mass, BMI and lean body mass. These findings likely reflect HIV disease severity and cachexia prior to ART initiation and the return to health phenomenon in patients with more advanced disease.

In the present study, we demonstrated an average increase in lean body mass among all participants by 96 weeks, with no significant difference between NRTIs but a trend towards greater gain in those assigned to ATV/r compared to EFV. Prior studies of ART initiation or change in ART found an increase in lean body mass when using older treatment regimens (primarily zidovudine or stavudine based) [14, 16, 27, 28] despite the potential for the thymidine NRTIs to induce mitochondrial toxicity in the muscle tissue [29, 30]. Our randomized study reports an increase in lean body mass for the first time with contemporary first-line ART regimens [31]. Observational cohorts including both ART-treated and ART-naïve populations demonstrate stable [32] or increased lean body mass over time, particularly among those on ART [33–35]. However, these findings have not been consistent across observational cohorts as other studies have demonstrated a decrease in lean body mass [36, 37].

Low bone mineral density and its resultant bone fractures are more prevalent in HIV-infected subjects on ART compared to HIV-uninfected populations [38]. The etiology of low bone mineral density is unclear but is likely multifactorial. In cross-sectional and longitudinal data of older, HIV-uninfected individuals (primarily women), greater lean body mass and fat mass are associated with greater bone mineral density [1, 6, 39]. Furthermore, cross-sectional studies suggest that total body mass may be one of the most significant determinants of bone mineral density of HIV-infected persons [9, 10, 13]. A cross-sectional study of 221 HIV-infected men (85% on ART) found that weight, lean body mass, total fat mass, and limb fat were significantly higher among men with normal bone mineral density; older age, lower lean body mass, and greater stavudine exposure were independently associated with lower bone mineral density in multivariate regression [40]. A recent publication from the Women's Interagency HIV Study cohort (83% on ART) measuring change in bone mineral density over a 5 year period found that among both HIV-infected and uninfected women, higher lean body mass was associated with increased bone mineral density at the lumbar spine, total hip, and femoral neck and that higher total body fat was associated with increased bone mineral density at the total hip and femoral neck [41].

Consistent with these studies, we demonstrate for the first time in a randomized ART-initiation study that the increase in lean body mass over 96 weeks was associated with an increase in hip bone mineral density. Surprisingly, we found that increased lean body mass was associated with greater bone loss at the lumbar spine, although this association was not seen in the multivariable analyses. Furthermore, increased visceral fat over 96 weeks was associated with increased bone mineral density at the hip but associated with decreased bone mineral density at the lumbar spine. The association of visceral fat on hip bone mineral density that we observed may be the result of the mechanical loading effect. Indeed, other studies have demonstrated an increased hip bone mineral density among both men and women with central obesity [42–44]. Similarly, these studies and others found no correlation or a negative correlation between direct or surrogate markers (waist circumference) of visceral adipose tissue and lumbar spine bone mineral density [44–46]. The negative association of adipose tissue with lumbar spine bone mineral density is hypothesized to be the result of pro-inflammatory cytokines [47].

As demonstrated in the Table 3 univariate analyses, week 96 changes in weight, BMI, and lean body mass were significantly associated with week 96 changes in both hip and lumbar spine bone mineral density. Furthermore, randomization to TDF/FTC led to a greater percent decrease in both hip and lumbar spine bone mineral density at 96 weeks compared to ABC/3TC, and ATV/r led a greater percent decrease in lumbar spine bone mineral density change at 96 weeks compared to EFV (previously published [23]). Because of these findings and the significant difference between ATV/r and EFV on week 96 change in weight and BMI presented here, we feel that the effect of the NNRTI/PI component on lumbar spine

bone mineral density change may be mediated through changes in weight, BMI, lean body mass or another factor associated with both weight and bone mineral density change. In addition to the body composition factors presented here, additional metabolic and HIV-related factors could be incorporated using structural equation models or causal mediation analysis to fully assess direct and indirect effects of regimen components.

The study has several limitations. First, the duration of follow-up for bone endpoints was relatively short and the impact of ART or body composition changes on bone mineral density could take several years. Second, the study population was relatively young for bone measures and results may not be applicable to older HIV-infected populations. Third, assignment of ATV/r versus EFV was not blinded and changes in the NRTI backbone occurred relatively frequently. However, the intent-to-treat results were consistent with the as-treated results, suggesting that changes in the backbone regimens do not explain our results. The A5224s study did not collect smoking, alcohol, menopause status, or physical activity data which could affect body composition measures, but it is likely that these were evenly distributed at baseline between treatment arms given the randomized study design. Finally, a large number of analyses were performed without adjustment, increasing the probability of committing one or more type I errors, and therefore results should be interpreted with caution. However, this was an exploratory analysis and it will be important for our findings to be confirmed in other studies.

In summary, our study shows that assignment to ATV/r leads to greater gain in body weight and BMI than EFV. Although overall gain in lean body mass was observed, there were no significant differences in lean body mass gain between NRTI or NNRTI/PI components. Furthermore, we found both an independent effect of NRTIs and a positive association of increased lean body mass with change in hip bone mineral density. These findings support the role of lifestyle interventions such as resistance exercise and nutrition to increase lean mass in order to potentially attenuate the initial decline in bone mineral density observed with ART initiation. Prospective studies are needed to assess the role of such lifestyle interventions.

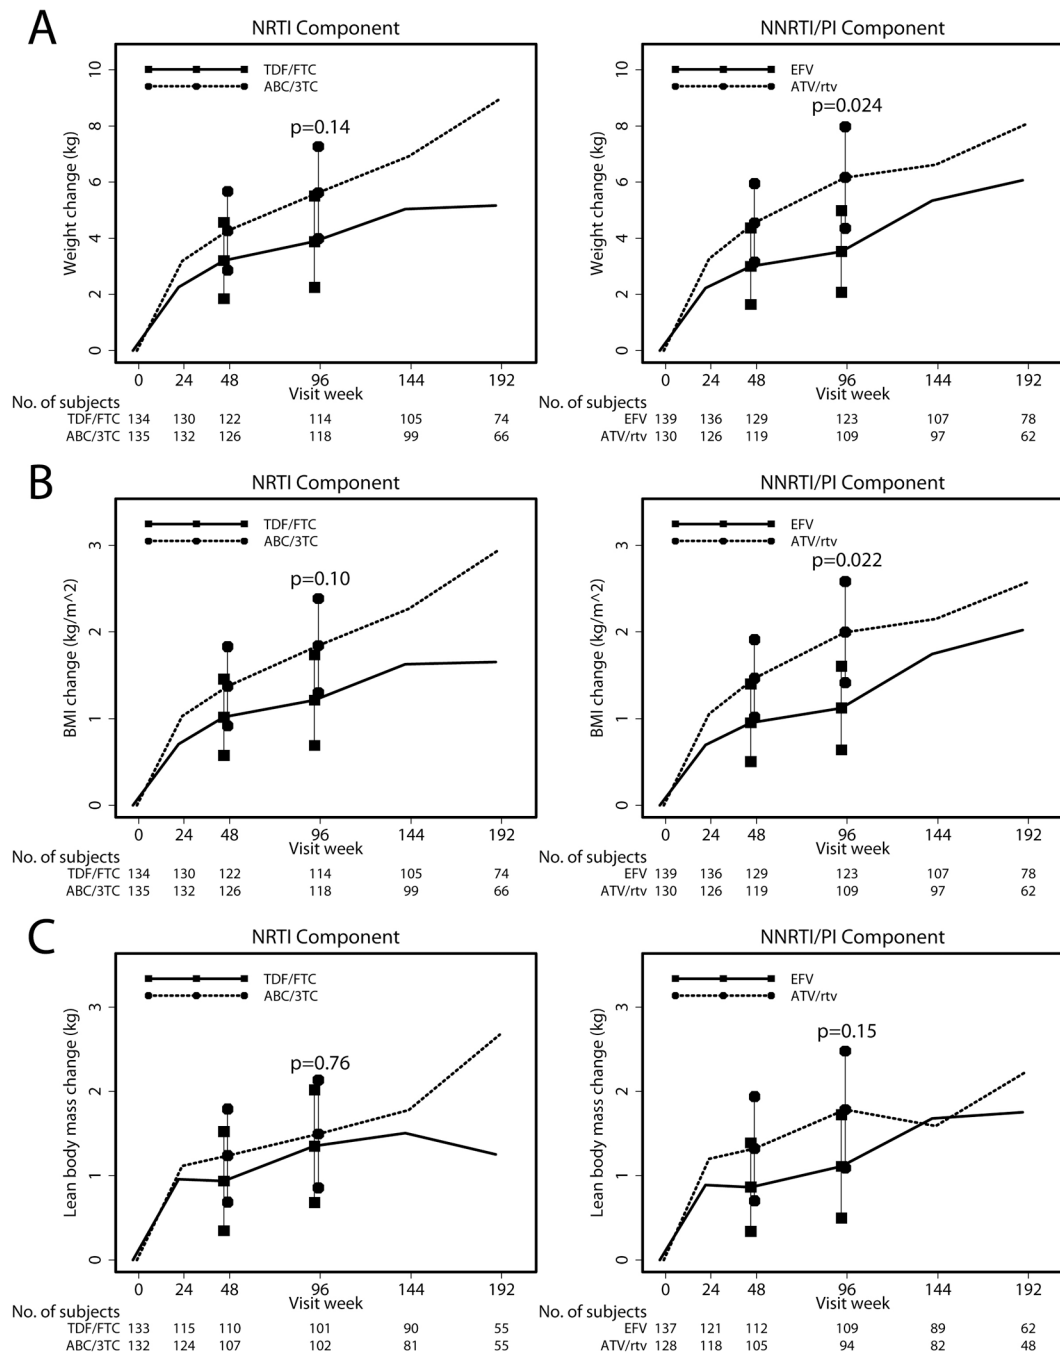

Figure 1.
Absolute changes in total weight, body mass index, and lean body mass by treatment arms. Mean and 95% confidence intervals are represented by symbols and error bars; P value from comparison between arms at 96 weeks; TDF/FTC, tenofovir-emtricitabine; ABC/3TC, abacavir-lamivudine; EFV, efavirenz; ATV/r, atazanavir-ritonavir. *A*. Changes in total weight between the nucleoside reverse transcriptase inhibitor (NRTI) and non-nucleoside reverse transcriptase inhibitor/protease inhibitor (NNRTI/PI) components. *B*. Changes in body mass index between NRTI and NNRTI/PI components. *C*. Changes in lean body mass between NRTI and NNRTI/PI components.

Table 1

Baseline characteristics of Study Participants

Characteristic	EFV + TDF/FTC N=69	EFV + ABC/3TC N=70	ATV/r + TDF/FTC N=65	ATV/r + ABC/3TC N=65	Total N=269
Age (years)	39 (10)	39 (10)	38 (10)	37 (10)	38 (10)
	40 (33–44)	39 (31–46)	38 (30–44)	37 (29–43)	38 (31–44)
Sex					
Male	58 (84)	56 (80)	56 (86)	59 (91)	229 (85)
Female	11 (16)	14 (20)	9 (14)	6 (9)	40 (15)
Race/ethnicity					
White non-Hispanic	37 (54)	34 (49)	26 (40)	29 (45)	126 (47)
Black non-Hispanic	22 (32)	20 (29)	21 (32)	27 (42)	90 (33)
Hispanic	8 (12)	14 (20)	14 (22)	8 (12)	44 (16)
Other	2 (<1)	2 (<1)	4 (1)	1 (<1)	9 (<1)
CD4 T-cell count (cells/μL)	248 (160)	231 (167)	226 (142)	238 (189)	236 (165)
	250 (132–334)	213 (106–350)	247 (114–319)	222 (75–332)	233 (106–334)
