ORIGINAL ARTICLE

The immune profile associated with acute allergic asthma accelerates clearance of influenza virus

Amali E Samarasinghe[1,2,3], Stacie N Woolard[2,4], Kelli L Boyd[5], Scott A Hoselton[6], Jane M Schuh[6] and Jonathan A McCullers[1,2,3]

Asthma was the most common comorbidity in hospitalized patients during the 2009 influenza pandemic. For unknown reasons, hospitalized asthmatics had less severe outcomes and were less likely to die from pandemic influenza. Our data with primary human bronchial cells indicate that changes intrinsic to epithelial cells in asthma may protect against cytopathology induced by influenza virus. To further study influenza virus pathogenesis in allergic hosts, we aimed to develop and characterize murine models of asthma and influenza comorbidity to determine structural, physiological and immunological changes induced by influenza in the context of asthma. *Aspergillus fumigatus*-sensitized and -challenged C57BL/6 mice were infected with pandemic H1N1 influenza virus, either during peak allergic inflammation or during airway remodeling to gain insight into disease pathogenesis. Mice infected with the influenza virus during peak allergic inflammation did not lose body weight and cleared the virus rapidly. These mice exhibited high eosinophilia, preserved airway epithelial cell integrity, increased mucus, reduced interferon response and increased insulin-like growth factor-1. In contrast, weight loss and viral replication kinetics in the mice that were infected during the late airway remodeling phase were equivalent to flu-only controls. These mice had neutrophils in the airways, damaged airway epithelial cells, less mucus production, increased interferons and decreased insulin-like growth factor-1. The state of the allergic airways at the time of influenza virus infection alters host responses against the virus. These murine models of asthma and influenza comorbidity may improve our understanding of the epidemiology and pathogenesis of viral infections in humans with asthma.

Asthma is a multifactorial disease of the airways that precipitates from genetic predisposition and environmental triggers. The World Health Organization estimates that 235 million people have asthma and an additional 100 million will develop the disease over the next 15 years.[1] In allergic asthma, exposure to environmental stimuli results in elevated serum immunoglobulin E, acute airway hyperresponsiveness (AHR), eosinophilic peribronchovascular inflammation and goblet cell (GC) metaplasia with associated mucus hypersecretion together with chronic airway remodeling, which includes angiogenesis, subepithelial fibrosis and smooth muscle cell hyperplasia.

Asthma has long been appreciated as a risk factor for hospitalization because of influenza, and asthmatics were a key target group for administration of influenza vaccines in the United States even before the 2010 recommendation for universal vaccination.[2] This association was highlighted during the 2009 H1N1 influenza pandemic.[3] Several recent studies reported asthma prevalence in 6–18% of children and adults hospitalized with seasonal flu and 14–30% in those

hospitalized with pandemic influenza.[4–6] Surprisingly, despite the high rate of hospitalization, asthma was associated with lower rates of pneumonia, intensive care unit admission, mechanical ventilation and death.[3–5,7–9] Reasons for these seemingly contradictory outcomes in asthmatics that develop symptomatic influenza are unclear, but they are of obvious scientific and public health interest.

Animal models of comorbidity are crucial in understanding host–pathogen interactions, which may improve patient care and increase successful medical outcomes. Existing murine model systems of asthma and respiratory virus comorbidity use influenza virus as an inducing agent for asthma development,[10] but have not examined the pathogenesis of influenza in established models of allergic asthma. As acute asthma (AA) and chronic asthma (CA) are considerably different syndromes requiring different interventions, there is a need for models that recapitulate the manner in which these types of allergic airways respond to respiratory pathogens. This void in model systems provided the impetus for our work. We previously

reported a mouse model that mimics the characteristics of acute inflammatory asthma soon after fungal challenge; the mice later undergo architectural changes that are characteristic of CA with the resolution of inflammation over time.[11,12] Using these models of allergic asthma as platforms, herein, we questioned how influenza virus impacts hosts with characteristics of either AA (marked by AHR, inflammation and GC metaplasia) or CA (marked by airway remodeling). These models serve as a basis to understand the immunological responses of the asthmatic host and may aid in the development of strategies to protect asthmatics from respiratory viral infections.

RESULTS

Asthmatic bronchial epithelium is protected from influenza virus-induced damage

To explore potential differences that allow for better outcomes in asthmatics hospitalized with influenza, we used primary human bronchial epithelial cells from healthy and asthmatic donors grown in an air–liquid interface to determine whether differential susceptibility was observed and, if so, whether it was due to differences in viral replication and/or cell sloughing. Cells from both donors were fully differentiated with pseudostratified morphology and mucus-producing cells (Figure 1a). After pandemic H1N1 (pH1N1) infection, cells from the healthy donor appeared squamous, while the morphology of cells from the asthmatic donor were unaffected by virus infection (Figure 1a and Table 1). We found no difference in viral titers between donors (6.5 ± 0.2 vs 6.8 ± 0.1 median dose infectious dose for 50% of tissue culture wells ($TCID_{50}$) ml^{-1}), although viral infection resulted in higher mucus gene expression and protein production in healthy cells (Figure 1b).

As the innate immune mediators of the epithelial barrier are crucial to the host's antiviral defense, we examined whether the cells from the asthmatic donor were protected from damage due to enhanced expression of antiviral factors. Expression of both TLR-3 and IL-1α were higher in healthy donor cells following viral infection (Figure 1c). Taken together, these data suggest that epithelial cells from the asthmatic donor are equally susceptible to pH1N1 infection but are resistant to virus-induced damage, possibly through reduced production of inflammatory cytokines such as

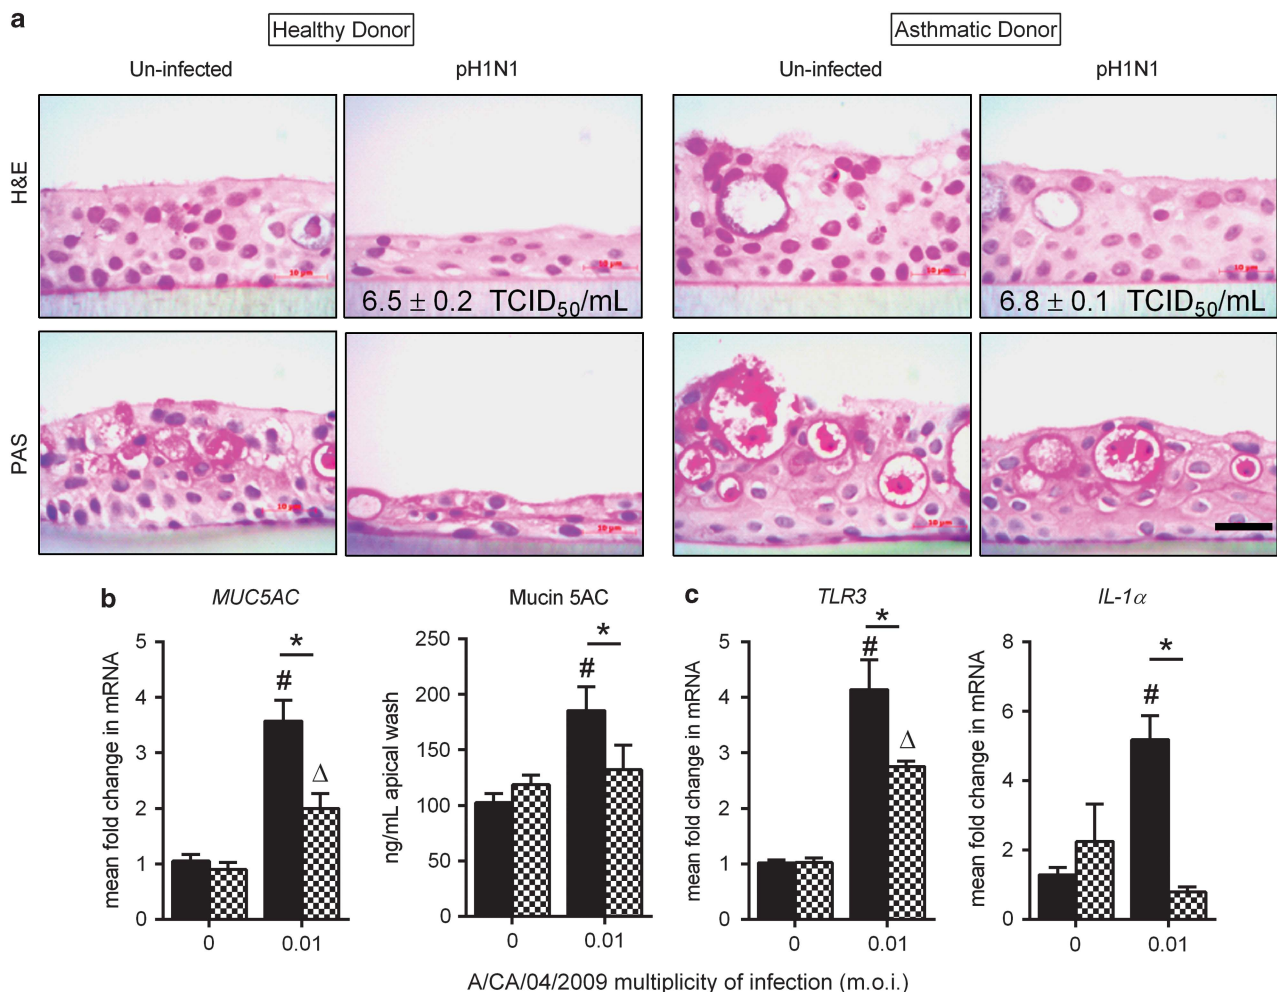

Figure 1 Human bronchial epithelial cells from healthy and asthmatic donors grown in the air–liquid interface infected with pH1N1 influenza virus at 0.01 m.o.i. Cells from both donors maintained a pseudostratified morphology and produced mucus under steady state. The thickness of the epithelial layer from the healthy donor was reduced and appeared squamous after pH1N1 infection, while cells from the asthmatic donor maintained normal morphology (a). Viral replication was comparable between cells (inset values, b). Cells from the healthy donor (solid bars) produced more mucus (b) and expressed more TLR3 and IL-1α after virus infection compared to asthmatic donor cells (checkered bars) (c). Data are presented as the mean and s.d. from a representative experiment, Δ,#$P < 0.05$ compared with uninfected control and *$P < 0.05$ by Student's t-test. Top panel hematoxylin and eosin (H&E) staining; bottom panel, periodic acid Schiff's (PAS) staining. Scale bar = 10 μm.

Table 1 Histological analyses of primary human bronchial epithelial cells from healthy and asthmatic donors grown in the air–liquid interface

Donor	Group	Effects on tissue structure
Healthy	Uninfected	Apical surface intact with visible cilia. Basal cells intact with healthy morphology. Pseudostratified cells with some PAS⁺ cells and acinar-like structures
	Infected with A/CA/04/2009 (pH1N1)	Apical cells detached with cell sloughing. Tissue thinned and more squamous morphology. Very few PAS⁺ cells present
Asthmatic	Uninfected	Apical surface intact with visible cilia. Basal cells intact with healthy morphology. Pseudostratified cells with many PAS⁺ cells and acinar-like structures
	Infected with A/CA/04/2009 (pH1N1)	Apical surface intact with visible cilia. Basal cells intact with healthy morphology. Pseudostratified cells with many PAS⁺ cells and acinar-like structures. Tissue appears slightly more compacted than uninfected controls

IL-1α. These findings provided a rationale for more in-depth studies in mice.

Stage in allergic asthma pathogenesis alters influenza morbidity

Two murine models were created by infecting mice during different stages of allergic asthma pathogenesis (Figure 2A): a fungal asthma model where mice were infected with pH1N1 during peak acute inflammation (AA + Flu; Figure 2Aa) and a fungal asthma model where mice were infected with pH1N1 during chronic remodeling (CA + Flu; Figure 2Ab). Histological images are representative of the state of the large airways in the allergen-challenged mice at the time of virus infection (Figure 2A). Weight loss was used as an indicator of influenza morbidity. Naive mice did not lose weight in either model, while flu-only controls gradually lost weight until day 8 with peak weight loss of 12–15% before recovery (Figure 2B). AA + Flu mice maintained weight throughout the model, while CA + Flu mice lost weight after infection, mimicking their flu-only counterparts (Figure 2B). Viral load in lungs peaked at day 3 and remained high through day 7 in flu-only controls, correlating with peak weight loss (Figure 2B). Viral titers in the AA + Flu group were decreased at this time point, indicating accelerated viral clearance; this was not observed in the CA + Flu model (Figure 2B). These data indicate that the allergic state of the airways at the time of influenza virus infection affects viral pathogenesis marked by body weight loss and viral replication.

As viral infection causes symptomology that may mimic asthma episodes,[13] and respiratory viruses such as rhinovirus and respiratory syncytial virus have been shown to induce asthma, we measured the resistance in the conducting airways (Rn) and changes in tissue parameters, tissue damping (G) and tissue elastance (H), in the models. Mice in the flu-only control groups of both models responded to methacholine challenge with values and trends equivalent to the AA + Flu groups (data not shown). However, responses in the CA + Flu groups were lower than in the AA + Flu group (Figure 2C). Thus, the allergic state of the airways at the time of virus introduction alters the physiological response of the lungs to virus infection. We investigated airway immune profiles next, because inflammatory cells and their products can cause pathophysiological changes.

Cell recruitment patterns differed between acute and chronic models after influenza

Lung inflammation occurs in asthma and respiratory infections, albeit with different types of immune cells taking precedence. There were threefold more cells in the airways at day 0 in AA compared with that of the CA model and naive controls (Figure 3). A reduction in cell

infiltration occurred over time after virus in the AA + Flu model but not in the CA + Flu model (Figure 3). Peak airway inflammation of flu-only controls occurred at day 7 (Figure 3), coinciding with sustained viral replication in these mice (Figure 2).

Influenza virus is known to induce neutrophil and T-cell recruitment, and this was seen in both 'flu-only' control groups (Figure 3). Eosinophils, which were prominent in AA airways, continued to increase after viral infection (Figure 3a), but did not change in the CA + Flu (Figure 3b). The AA + Flu model had fewer neutrophils and equal compositions of macrophages and CD4⁺ lymphocytes compared with the CA + Flu model. Although the total number of CD8⁺ lymphocytes in the airways of both models was similar, pH1N1-specific CD8⁺ T cells were more abundant in AA + Flu (Figure 3). These data suggest that the existing allergic state of the airways has an impact on immune cell recruitment following pH1N1 infection.

Mice in the chronic model, including the flu-only controls, exhibited a reduced phenotype for weight loss, although viral titers were roughly equal to that in the acute model (Figure 2B). The reduction in inflammatory cells was observed in the flu controls age matched to the CA + Flu compared with those age matched to the AA + Flu (Figure 3). Although the difference between the two groups at the time of viral infection was 3 weeks, immune function was likely different because these ages fell at the exponential decline phase of thymic involution,[14] highlighting the importance of mouse age in studies with infectious agents.

Histopathology of lungs differed between the acute and chronic models of comorbidity

Structural damage to the airways is a characteristic of influenza.[15] Virus infection resulted in peribronchovascular inflammation in both models of comorbidity. Inflammatory foci in the peribronchovascular areas peaked 5 days after pH1N1 infection in AA + Flu lungs (Figure 4 and Table 2A) coinciding with the viral plateau (Figure 2). There was a delay in the recruitment of inflammatory cells into the CA + Flu airways (Figure 4 and Table 2B). Although influenza virus is cytopathic, we noted that morphological changes in bronchial epithelia were only apparent in the flu controls and CA + Flu but not in AA + Flu airways (Figure 4 and Table 2).

Mucus production is an important innate defense in the respiratory tract. Virus alone did not induce GC metaplasia, while both GC metaplasia and *Muc5AC* were increased in the comorbid states (Figure 5). Although *Muc5AC* levels decreased after viral infection in both groups, the number of GCs remained elevated, suggesting that other mucin genes may have a supplementary role in comorbidity. The abundance of GCs and induction of *Muc5AC* expression in AA + Flu may have served as an additional innate defense that
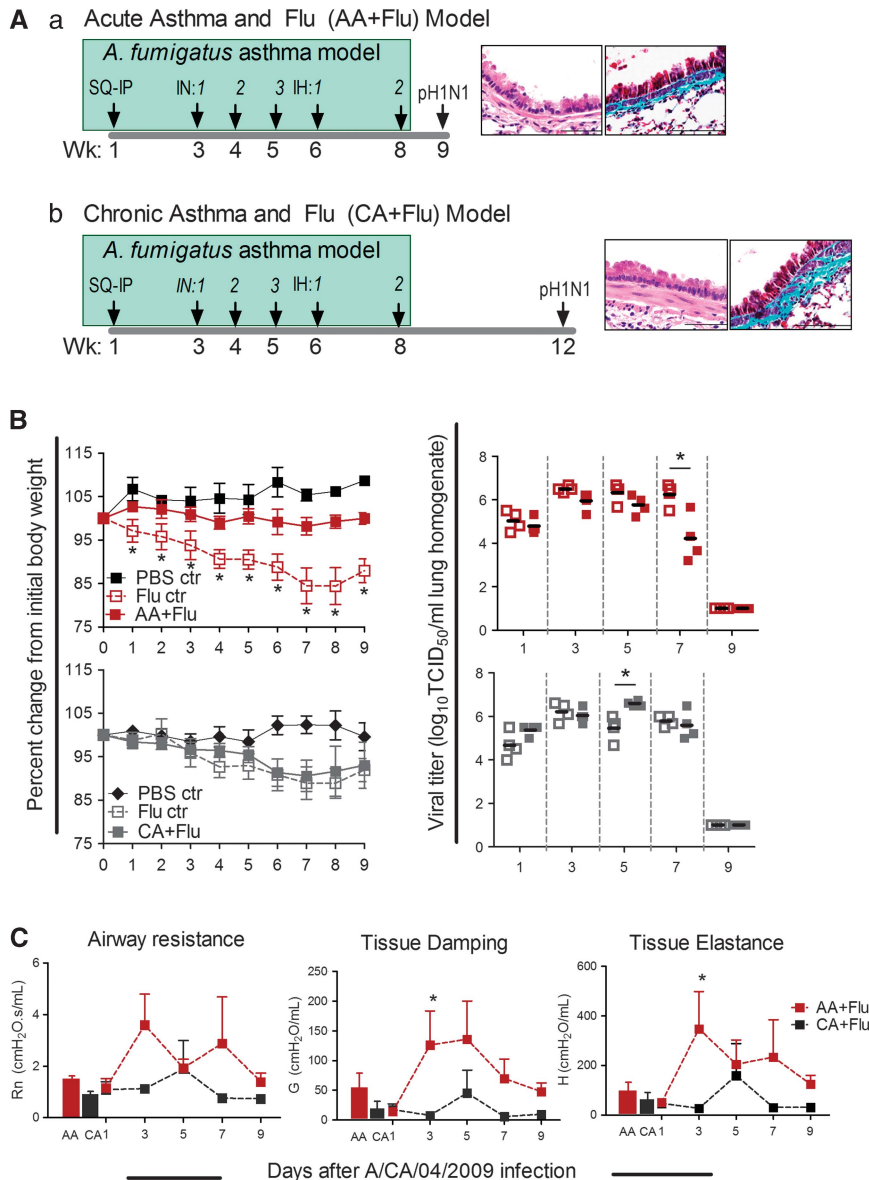

Figure 2 The developmental stage of allergic asthma impacts influenza morbidity. Schema of comorbidity models (**A**): (a) AA + Flu and (b) CA + Flu. Images represent the level of airway remodeling in AA and CA lungs at the time of infection. Weight loss and viral titers were affected by the state of allergy in lungs (**B**, $n = 8$–9 per group). Airway physiological parameters including Newtonian resistance (Rn), tissue damping (G) and tissue elastance (H) were reduced in the CA + Flu model compared with that of AA + Flu (**C**, $n = 4$ per group). Data are representative of two independent experiments and presented as the mean and s.d., *$P < 0.05$ by analysis of variance. protected these mice from influenza. Taken together, these data infer that intact structural defenses of lungs may have contributed to protection from influenza in the AA + Flu model.

Host interferon response may contribute to influenza morbidity

As the interferon (IFN) system is implicated in antiviral defenses and virus-mediated tissue damage in the lungs,[16] we measured the host's local IFN response. The antiviral IFN response, as characterized by Type I (IFNα), Type II (IFNγ), Type III (IFNλ3/IL-28b) and IRF9 (IFN regulatory factor-9), was activated in flu-only controls. The peak in available IFNα and IFNγ in the bronchoalveolar lavage (BAL) fluid occurred at day 5 after infection in the CA + Flu model, while peak expression of IL-28b and IRF9 genes occurred at day 3 (Figure 6a). The Type I

and Type III IFN responses are initiated sooner during the viral growth curve in the flu-only control groups than in the asthma and flu groups, while the Type II system is initiated in the flu-only control groups at day 7 (Figure 6a). Nonetheless, unlike the other parameters measured, pH1N1 infection triggered an IFN response in the CA + Flu groups compared with the AA + Flu groups (Figure 6a). An opposing trend in levels of the proinflammatory molecule insulin-like growth factor-1 (IGF-1) was observed between the two models (Figure 6b). IGF-1 was prominent before viral infection in allergic mice during the acute inflammatory phase, but not the chronic remodeling phase, and was induced late in the course of infection by influenza virus in both allergen-naive and CA + Flu models. These data suggest that canonical IFN pathways are not responsible for improved outcomes in acute, allergic asthma,
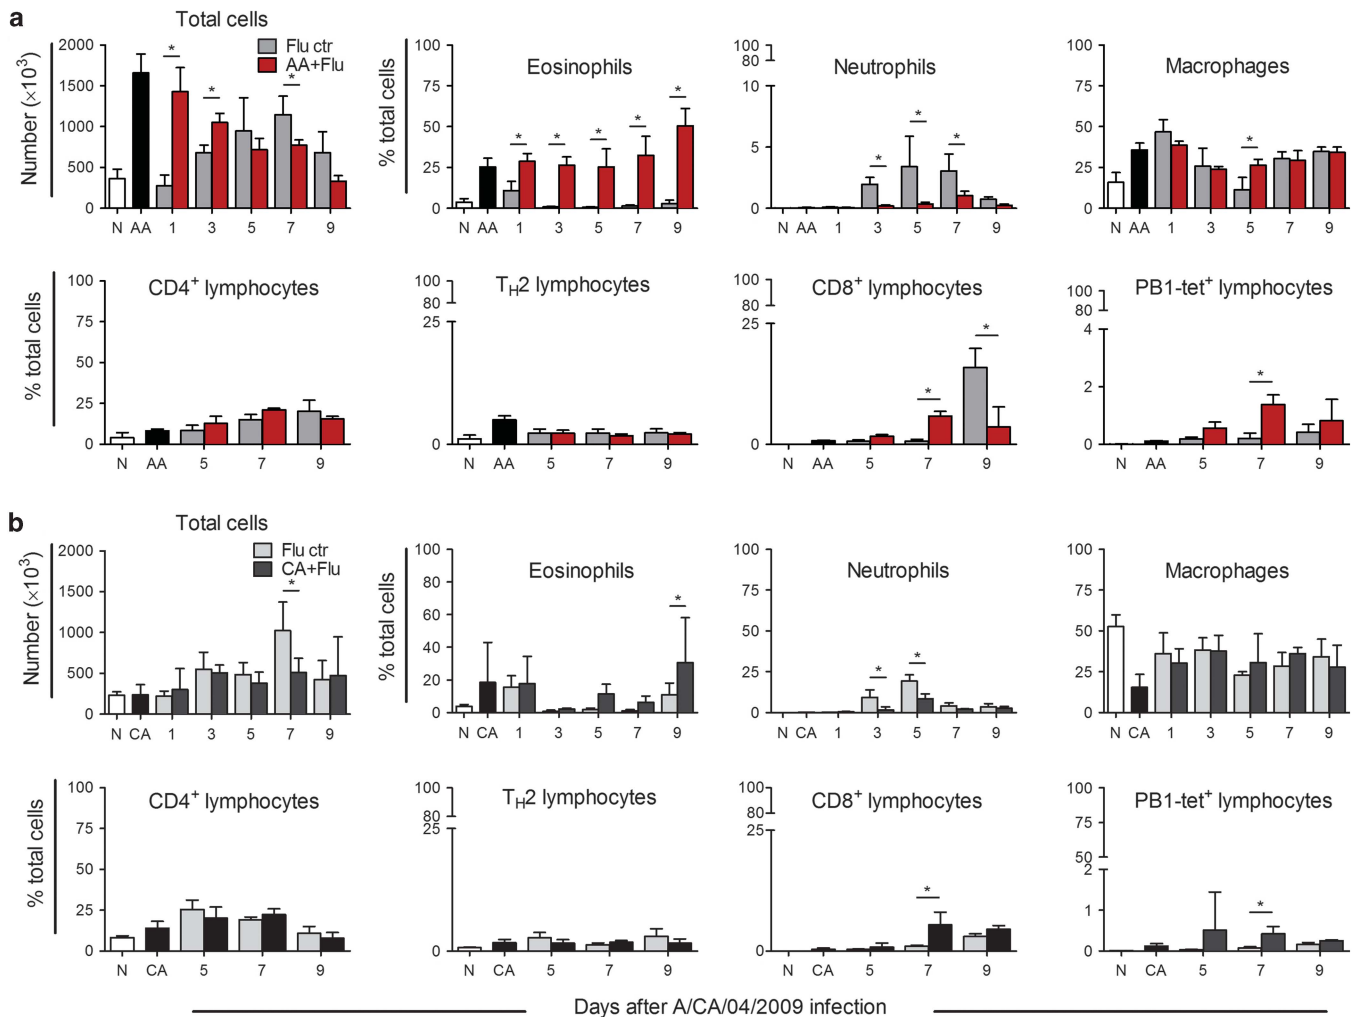

Figure 3 Inflammatory cell recruitment into the airways after pH1N1 infection. There were more cells recruited into the AA + Flu airways, particularly eosinophils and flu-specific CD8+ T cells (**a**). The influx of cells was reduced in the CA + Flu airways, wherein macrophages made up a large proportion (**b**). Data are representative of two independent experiments and presented as the mean and s.d., $n = 5$ mice per group and *$P < 0.05$ by analysis of variance. Ctr, control; T_H2, T helper type 2. N, naive.

but highlight a potential relationship between IGF-1 and asthma that may mediate protection from influenza.

DISCUSSION

Asthma, a complicated disease involving multiple intrinsic and extrinsic parameters, is a major underlying condition associated with respiratory infections. Clear clinical and epidemiological data demonstrate that asthmatics are at high risk of hospitalization during influenza epidemics; however, recent studies show that asthmatics were less likely to die from pH1N1 and suffer less severe symptoms and outcomes once hospitalized.[3–5,7–9] As the existing models typically utilize influenza viruses as initiators or exacerbators of asthma in mice,[17,18] the question of how the asthmatic hosts' immune response to influenza differs from that of the normal host has not been previously addressed. In this study, we developed models of comorbidity by combining a murine model that recapitulates the hallmarks of human asthma[11,12,19] with a model of influenza A virus infection.[20] Using these, we have found that the inflammatory state of the host's allergic airways has a fundamental role in influenza pathogenesis. Our study shows that acute allergic airways are

protected from influenza, supporting a hypothesis proposed by Chang et al.[17] to explain why in some cases respiratory viruses inhibited asthma, while in other cases asthma development was promoted. This is also strengthened by a recent report showing improved outcomes in ovalbumin-sensitized mice challenged with a mouse-adapted lab strain of influenza.[21]

Respiratory viruses are the leading cause of asthma exacerbations in children and adults.[22] A prospective study during the 2009 influenza pandemic showed that pH1N1 preferentially infected asthmatics more than non-asthmatics, which the authors speculated may be due to impairments of the bronchial epithelium.[23] However, our findings show that there was no difference in viral replication capacity in epithelia from healthy/asthmatic donors. In fact, cells from the healthy donor were more susceptible to pH1N1-mediated cytopathology, findings that were recapitulated in our murine models, wherein the airway epithelia of AA + Flu were intact, while that of the flu controls and CA + Flu were damaged. The respiratory epithelium performs crucial physical and innate immune defenses against environmental pathogens through mucus, reactive oxygen species, defensin and cytokine production.[24,25] Although asthmatic

lungs have mucus-producing cells and mucus hypersecretion, our data with *ex vivo* human tissues suggest that mucus production in response to virus may require a higher viral burden in asthmatics. As virus-induced activation of TLR3 on epithelial cells promotes proinflammatory cytokine production leading to tissue injury,[26] and IL-1α can promote cytopathology in epithelial cells,[27] the induction of *TLR3* and *IL-1α* in cells from the healthy donor may have contributed

to the enhanced susceptibility to pH1N1-induced damage. Because we noted a similar protection in the airway epithelia of the AA+Flu group, a specific mechanism may be in place to signal cell survival in spite of viral replication in asthma. Further analyses into the barrier functions of epithelial cells will help elucidate the mechanism in which epithelia from asthmatics maintain structural integrity in the presence of a cytolytic pathogen such as influenza A virus.
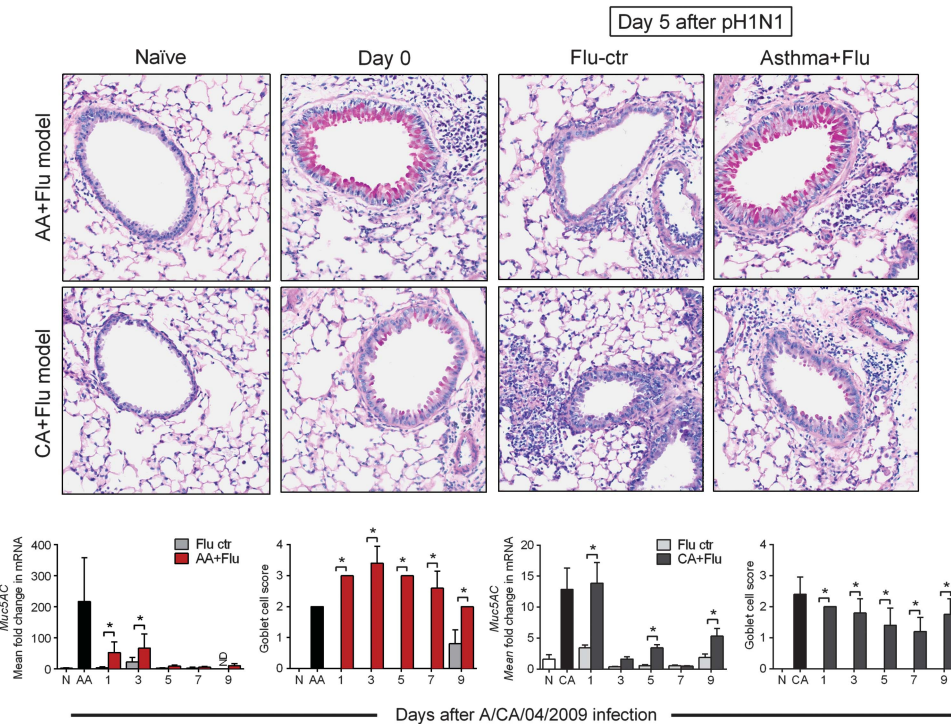

Figure 5 Presence of GCs in the airways of mice after pH1N1 infection. Virus infection alone did not induce GC metaplasia. More GCs were noted in the AA + Flu compared with CA + Flu. Representative images are at × 400 after periodic acid Schiff's staining. Although *Muc5AC* gene expression was reduced, the number of GCs that interspersed the airways remained elevated in the comorbidity groups. Data are representative of two independent experiments and presented as the mean and s.d., $n = 5$ mice per group and *$P < 0.05$ by analysis of variance. Ctr, control.

In addition to the structural integrity of airway epithelium and inflammatory cells, respiratory viruses also induce changes in lung physiology.[28] Our findings support the growing literature that these parameters are not merely reflective of airway smooth muscle stiffness/shortening, but that they are complex phenomena that are indicative of the state of the airways such as airway narrowing (which may be due to mucus or cells), increased epithelial thickness and vascular leakage.[29] The role of eosinophils in AHR has been debated in the past, wherein their presence has been demonstrated both as necessary[30] and unnecessary[31] for AHR. Our data demonstrate that changes in airway physiological parameters, Rn, G and H, can occur in the absence or limited number of eosinophils as in the flu-only control groups and CA + Flu, respectively, as well as in their presence as in AA + Flu. The increase in Rn that resulted because of pH1N1 alone possibly involved other pathways that increase airway resistance such as IL-1β and IL-13,[32,33] which were elevated in these mice (data not shown). As the flu-only control animals had airway responses equivalent to AA + Flu groups in spite of having less immune cell recruitment, the reduction in lung physiological parameter of the CA + Flu group cannot be due to reduced immune infiltrates. This non-responsiveness in the CA + Flu groups is interesting, and may be explained by the 'inflammatory twitch' theory recently proposed by Pothen et al.[34] In the CA + Flu model where the influenza virus infection occurred during the resolution/refractory phase of the allergic inflammatory response, we propose that the lung was not primed to mount a second response to the invading pathogen. This 'unprepared' state of the chronic allergic lung, marked by reduced inflammation, and lack of pathophysiologic changes, may have then given way to the increased pathogen burden (Figure 2) and host pathology (Figure 4), which were observed in the CA + Flu model.

Antiviral immunity is associated with the recruitment of neutrophils[35] and virus-specific CD8[+] T cells.[36] Our findings that AA + Flu mice were protected from influenza likely reflect the importance of virus-specific CD8[+] T cells in viral clearance. As neutrophils were absent in the AA + Flu lungs, their potential antiviral role may have been performed by another granulocyte that was abundant, the eosinophil. Functions of eosinophils that transcend that of the traditional antiparasitic role[37] such as antigen presentation,[38] phagocytosis,[39] antiviral[40] and antibacterial[41] defense advocate for a direct or indirect antiviral role of eosinophils in allergic asthma and influenza comorbidity. Influenza virus has been previously shown to hinder the recruitment of eosinophils and T helper type 2 cells into airways after allergen challenge.[42] This reduction of hallmark T helper type 2 immunity is linked increased IFNγ and CD8[+] T cells following influenza virus infection.[43] We did not observe an inhibition of T-cell or eosinophil recruitment following viral infection in our models, further suggesting that the manner in which influenza virus impacts the allergic airways may be linked to the pre-existing immunological state of the lung and the microenvironment of the airways.

Infiltrating cells produce cytokines that direct the defense mechanisms in the lungs against influenza. Type I and Type II IFNs have a vital role in viral immunity, as well as the immunopathology associated with influenza.[44,45] Type III IFNs (IFNλ) are recently discovered conserved genes with three members.[46] For these studies, we focused on IFNλ3 (IL-28b) because the IFNλ1 is absent in mice[47] and IFNλ2 and -3 are homologous. As certain proteins are shared between the Type I and Type III IFN systems, we looked at IRF-9 as a common upstream indicator of viral-induced IFN gene expression. Herein, we noted that IFN Types I–III were not induced by influenza A virus infection in the AA + Flu model, while mice in the CA + Flu groups responded to viral infection with IFN Type I and III

Figure 6 Host immune factors were altered in the lungs following pH1N1 infection. Viral infection results in reduced IFNs and their downstream factors in AA + Flu, while levels in CA + Flu were more equivalent to flu-only controls (**a**). An opposing trend was observed for IGF-1 between the AA + Flu model and flu-only controls. IGF-1 levels in the BAL fluid followed the same trend between the CA + Flu and flu-only controls (**b**). Data are representative of two independent experiments and presented as the mean and s.d., *n* = 5 mice per group and *P < 0.05 by analysis of variance. production. As T helper type 2 cytokines in BAL fluid and lungs were equivalent between AA + Flu and CA + Flu (data not shown), the downregulation of IFNs in the AA + Flu model could not be attributed to an overexpression of T helper type 2 cytokines. Although the IFN response is mounted by the host as a primary antiviral defense mechanism, IFNs have a myriad of effects on host cells including increasing expression of major histocompatibility complexes and inducing cell death,[16,48] which can be detrimental to the

host. The CA + Flu model was more susceptible to pH1N1-mediated morbidity and had a higher viral burden in spite of inducing an IFN response. Therefore, we speculate that in the CA + Flu model, the induction of the IFN cascade may have resulted in the observed immunopathology in the airways (Figure 4) compared with the AA + Flu model in which IFNs were reduced.

Largely considered a hormone, IGF-1 has proinflammatory properties; its neutralization in allergen-challenged lungs led to decreased

immune cell infiltration and adhesion molecules and blocked AHR[49] and prosurvival properties of cells.[50] Yamashita et al.[49] demonstrated that airway epithelial cells were prominent producers of IGF-1 in the mouse lung. The reduced availability of IGF-1 in the CA + Flu model may have resulted from the damage induced in these cells by the invading virus, and may have partially contributed to the reduction in inflammation and AHR. Receptors for IGF-1 expressed on most immune cells signal proliferation or cytokine release.[51,52] Therefore, high availability of IGF-1 in the microenvironment of AA + Flu may have promoted survival and activation of recruited immune cells compared with CA + Flu model, which had reduced cell infiltration. Although not a direct goal of the present work described here, we are currently investigating the novel hypothesis that IGF-1 produced by the airway epithelial cells of mice in the AA model enhances antiviral defenses against influenza A virus infection in this mouse model (Figure 6c).

Asthmatics may be infected with respiratory viruses during the inflammatory or remodeling phases of the disease. The present study, aimed at generating and characterizing a mouse model of asthma and influenza comorbidity, has shown that the timing of influenza infection on pre-existing asthmatic airways affects the immunological, virological and histopathological outcomes. Our main finding that influenza morbidity differed based on the state of the allergic airways corroborates a human study in which rhinovirus infection did not worsen asthma symptomology.[53] Although precise information on the allergic state of the airways of the hospitalized asthmatics during the 2009 influenza pandemic is not readily available, clinical reports highlight that the highest mortality occurred in adults between 18 and 64 years of age.[54,55] Phenotypic differences between childhood and adult asthma as discussed in depth by Bush and Menzies-Gow[56] indicate that adult patients are more likely to have remodeled airways that may be more susceptible to respiratory pathogens. Model systems that can recapitulate the microenvironment of these patient subsets are necessary and can be used to further our understanding on infectious disease pathogenesis in allergic asthma. Those developed herein are ideally suited to investigate the pathways that protect asthmatics with acute airways inflammation from influenza virus and increase susceptibility in chronic asthmatics.

METHODS
Ethics statement
All experiments were approved by the Institutional Animal Use and Care Committee at St Jude Children's Research Hospital (SJCRH, Memphis, TN, USA).

Virus
Pandemic influenza virus A/CA/04/2009 (pH1N1) obtained from Dr Richard Webby at SJCRH was propagated in Madin–Darby canine kidney (MDCK.2; ATCC, Manassas, VA, USA) cells.

Primary bronchial epithelial cells
Fully differentiated primary bronchial cells from a healthy African-American 18-year-old female donor and an African-American 56-year-old female with asthma (MatTek Corporation, Ashland, MA, USA) were infected with low multiplicity of infection (m.o.i.) of 0.01 pH1N1 to mimic in vivo infections or left uninfected as controls.

Mice
Six-week-old C57BL/6 female mice from Jackson Laboratories (Bar Harbor, ME, USA) acclimatized for 1 week in SJCRH's specific pathogen-free ABSL2 facility with ad libitum food and water in a 12-h light:dark cycle and examined and weighed daily after infection.

Allergic asthma was induced in mice using *Aspergillus fumigatus* as previously described by our group.[11,19] Briefly, animals were sensitized to whole antigen from *A. fumigatus* extract from Greer Labs (Lenoir, NC, USA) adsorbed in Imject Alum (Pierce, Rockford, IL, USA) via subcutaneous and intraperitoneal injections. After a 2-week resting period, mice were administered 20 μg of *A. fumigatus* antigen in 20 μl intranasally once a week for 3 weeks. One week following the final intranasal delivery of antigen, anesthetized mice were exposed to live, unmanipulated, mature *A. fumigatus* conidia for 10 min via natural inhalation route. This fungal challenge was repeated 2 weeks later. The AA model is characterized by eosinophilic inflammation in the BAL spaces and peribronchovascular inflammatory foci, GC metaplasia, epithelial thickening, AHR to methacholine challenge and increased serum immunoglobulin E, all of which peak at 7 days after the fungal challenge. The CA model is characterized by airway remodeling events that begin to occur after 14 days following the fungal challenge, such as peribronchial smooth muscle hyperplasia and hypertrophy, and increased subepithelial fibrosis along with remnant peribronchovascular eosinophilic inflammation and serum immunoglobulin E. The characterization of this model system has been previously published by our group.[11]

Mice in the 'flu' groups were infected with pH1N1 virus at 1000 $TCID_{50}$ in a 50 μl inoculum intranasally. The infectious dose induced morbidity but no mortality. Mice in the 'naive' groups were administered saline in place of *A. fumigatus* antigen and pH1N1 virus.

Comorbidity models. AA + Flu groups were infected with pH1N1 virus 1 week after the second fungal inhalation challenge at the peak of allergic inflammation. CA + Flu groups were infected with pH1N1 virus 4 weeks after the second fungal challenge, at which point inflammation had subsided and airway remodeling events had progressed. As we anticipated nonsignificant changes in the inflammatory profile in the asthma-only groups over the 9-day period at the chosen time after the second fungal challenge, naive, 'AA'-only and 'CA'-only controls in each study were harvested on the day of viral infections. Mice in the AA + Flu and CA + Flu groups were 15 and 18 weeks of age, respectively, at the time of infection.

BAL and tissue harvest. BAL was performed on animals that were killed. Caudal and accessory lobes of the right lung were harvested and snap frozen for RNA quantification, while left lobes were harvested and infused ex vivo with 1 ml of 10% neutral-buffered formalin for histopathology.

Airway physiology
Anesthetized mice ($n = 4$ per group) were surgically intubated and attached to a computer-controlled small animal ventilator (flexiVent FX1; SCIREQ, Montreal, QC, Canada) data gathered by flexiWare software (SCIREQ) at a mouse default ventilation rate of 150 breaths min^{-1} using the 'mouse inhaled dose-response' script. After baseline, 25 mg ml^{-1} of acetyl-β-methacholine (Sigma, St Louis, MO, USA) was nebulized into airways for 10 s. Newtonian resistance (Rn), tissue damping (G) and elastance (H) were recorded. The mean of software-generated values after methacholine was calculated for each animal before obtaining the mean for each group.

Flow cytometric analysis of BAL cells
BAL cells were washed with staining media (sterile phosphate-buffered saline with 5% fetal bovine serum) and enumerated with the Countess (Invitrogen, Grand Island, NY, USA). All incubations were performed in ice in the dark, and the staining media were used to dilute antibodies and washings. One to two million cells were incubated for 30 min with human γ-globulin (blocks Fc receptors) and live–dead aqua (Invitrogen) at 1 μl per million cells to differentiate live cells from dead. Cells were washed and incubated in fluorescent-tagged antibodies from BD Biosciences (San Jose, CA, USA) at 1:50 for 30 min: CD8-FITC, CD3-PE-Cy7, CD107b (Mac3) -PE, CD193 (CCR3) -APC, Ly6G-V450, CD4-A700 and CD19-PerCP-Cy5.5. Cells were washed and fixed with BD stabilizing fixative (4% paraformaldehyde), and strained through a 40 μm nylon mesh into labeled polystyrene tubes and stored at 4 °C overnight before flow cytometry analysis the next day. Tetramer staining was performed on a separate set of mice ($n = 4$ per group) as

described above except staining cocktail included antibodies against CD3-PE-Cy7, CD4-A700, CD8-FITC and PB1-tetramer-PE (diluted 1:8000 per titration by the Thomas Lab at SJCRH). Each experimental sample group was accompanied with an unstained cell population, isotype controls and single-color controls for instrument and compensation setup. Cells from each mouse were analyzed individually, and the mean and standard deviation (s.d.) were calculated for each group ($n = 5$ per group). Data were acquired with a LSRFortessa (BD Biosciences) with 350, 405, 488, 561 and 641 nm lasers.

Samples were acquired and analyzed within the St Jude Children's Research Hospital Flow Cytometry Core. FMO (fluorescence minus one) controls are not required for staining protocols. Isotype controls are used to negate nonspecific binding and background noise. The fluorescence is compensated manually on both bone marrow cells and the tissue of investigation. The LSRFortessa in which these samples were acquired is subjected to a rigid quality control test each day to ensure that proper voltages are used for every experiment. The limiting factor within the experiments is the availability of the tetramer antibody. The tetramer with the highest stain index was selected for the subsequent experiments. Raw FCS files can be submitted at any time for further evaluation. The gating strategies used, determined based on the literature and known markers for various cell types, are demonstrated in the Supplementary Figures 1 and 2.

Histopathology
Paraffin-embedded tissue inserts or lungs were sectioned at 4 µm and stained with hematoxylin and eosin and periodic acid Schiff's stains. Slides were coded and read by a pathologist blinded to the study design (KLB).

RNA analysis
Harvested RNA from human bronchial cells and lungs was converted to cDNA (iScript; BioRad, Hercules, CA, USA) and was analyzed by quantitative polymerase chain reaction with RNA-specific Quantitect primer assays (Qiagen, Valencia, CA, USA) against human HPRT-1, TLR-3 and IL-1α and mouse HPRT-1, Muc5AC, IL-28b and IRF-9. Data were acquired with an ABI-7500 real-time PCR machine (Applied Biosystems, Carlsbad, CA, USA) and relative fold change in gene expression was determined using the $2^{-\Delta\Delta Ct}$ method normalized to the internal housekeeping gene, HPRT-1.

Quantification of specific proteins
To determine the impact viral infection has on the airway milieu, we measured proteins by enzyme-linked immunosorbent assays. We measured the amount of Mucin 5AC in the apical wash of primary bronchial cells with a precoated ELISA kit from CUSABIO (Wuhan, China). IFNα (pbl IFN Source, Piscataway, NJ, USA), IFNγ and IGF-1 (BD Biosciences) were measured in undiluted BAL fluid following the manufacturer's protocols.

Viral titration
Viral content in apical wash of cells or whole-lung homogenates was determined as the TCID$_{50}$ on Madin–Darby canine kidney cells.

Statistical analysis
Animal studies were repeated for reproducibility. Data are represented as the mean ± s.d. Data after virus infection were compared with naive controls with Student's t-test on GraphPad Prism (GraphPad Software, La Jolla, CA, USA) and $P < 0.05$ was considered significant and represented by '#' for cells from the healthy donor and 'Δ' for cells from the asthmatic donor. Data from the flu-only control groups and asthma + flu groups were compared by two-way analysis of variance and $P < 0.05$ was considered as significant and represented by an asterisk (*).
