**Forests in the middle and high latitudes of the northern hemisphere function as a significant sink for atmospheric carbon dioxide (CO<sub>2</sub>). This carbon (C) sink has been attributed to two processes: age-related growth after land use change and growth enhancement due to environmental changes, such as elevated CO<sub>2</sub>, nitrogen deposition, and climate change. However, attribution between these two processes is largely controversial. Here, using a unique time series of an age-class dataset from six national forest inventories in Japan and a new approach developed in this study (i.e., examining changes in biomass density at each age class over the inventory periods), we quantify the growth enhancement due to environmental changes and its contribution to biomass C sink in Japan's forests. We show that the growth enhancement for four major plantations was 4.0~7.7 Mg C·ha<sup>-1</sup> from 1980 to 2005, being 8.4–21.6% of biomass C sequestration per hectare and 4.1–35.5% of the country's total net biomass increase of each forest type. The growth enhancement differs among forest types, age classes, and regions. Our results provide, to our knowledge, the first ground-based evidence that global environmental changes can increase C sequestration in forests on a broad geographic scale and imply that both the traits and age of trees regulate the responses of forest growth to environmental changes. These findings should be incorporated into the prediction of forest C cycling under a changing climate.**

biomass carbon sink | forest age | forest inventory

**R**ecent studies indicate that forests in the middle and high latitudes of the northern hemisphere have functioned as a significant sink for atmospheric carbon dioxide (CO<sub>2</sub>) over the past decades (1–4). This carbon (C) sink results from two major processes: age-related growth (regrowth) after land use change and growth enhancement due to environmental changes (simply called “growth enhancement” hereafter), such as elevated CO<sub>2</sub>, nitrogen (N) deposition, and climate change (5–13). These two processes have contrasting implications for predicting the magnitude of future C sequestration in forest ecosystems. Forest C storage may be expected to saturate during the late stage of stand development if forests simply are regrowing after stand-replacing disturbance (14). In contrast, the future C storage potential of forests will be highly uncertain if tree growth has been altered by environmental changes (13, 15–17). Individual-level observation reveals that tree growth rate increases continuously with tree age or size for most tropical and temperate tree species (18), but environmental change, such as climate warming without an increase in precipitation, might reduce the growth rates of trees (19). Thus, knowledge of the relative contribution of tree regrowth and growth enhancement to C accumulation in forest ecosystems across a broad geographical scale is critical for predicting future C sequestration in land ecosystems and planning strategies to mitigate the increase of atmospheric CO<sub>2</sub> concentration (5, 11, 13, 20).

During the past decade, the relative contribution of these two mechanisms to C accumulation in forest ecosystems has received considerable attention (5, 6, 11, 12), but attribution between these two is largely controversial (7–9, 13, 15, 16) because of

a lack of available data and appropriate methodology (11, 21). For example, simulation results from land surface models revealed that growth enhancement might account for 25–75% of terrestrial C sink in the United States (6, 21), but ground-based studies demonstrated that only about 2.0% of the aboveground biomass increase was the result of environmentally enhanced growth in five states of the eastern United States (5). The conflicting results highlight that more observations are required to distinguish the relative contribution of tree regrowth and growth enhancement to C sequestration in forest ecosystems (11, 12).

Forest inventories, widely collected and designed to be statistically valid by many countries, are recognized as the best ground-based observations for quantifying the size, spatial patterns, and changes of forest C stock at regional, national, and global scales (22–24). Although the inventory data in most countries of the world cannot be used to evaluate the relative contribution of age-related tree regrowth and environmentally enhanced growth to forest C sink because of a lack of data on stand age, fortunately, those in Japan contain detailed information on stand age for major forest types for each region since the 1980s (for details, see *Materials and Methods*), and thus offer a unique opportunity to evaluate growth enhancement due to environmental change and its contribution to forest C accumulation at a large scale. Here, using a systematic, fine time series of age-class data obtained from six forest inventories (1980, 1985, 1990, 1995, 2000, and 2005) (25, 26) and forest type-specific biomass expansion factor

## Significance

**Northern forests have sequestered a substantial amount of carbon dioxide from the atmosphere during the past several decades. This large carbon (C) sink usually is considered to be driven by tree regrowth after stand-replacing disturbance and growth enhancement due to environmental changes, but the relative contribution between these two processes remains unclear. In this study, we evaluate the contribution of growth enhancement induced by environmental changes to biomass C sink in Japan's forests and demonstrate that this growth enhancement accounts for 8.4–21.6% of biomass C sink in four major plantations from 1980 to 2005. This finding highlights that global environmental changes can stimulate tree growth and thus enhance forest C sequestration over a broad geographical scale.**

**Fig. 1.** A conceptual diagram showing changes in biomass density induced by environmental change. (Left) Conceptually, environmental change may lead to (a) an increase, (b) no change, or (c) a decrease in biomass density of a forest stand at a given age class over different inventory periods. The assumption in the approach is that at a similar management regime over time, forest stands of similar age will have the same standing biomass, and any differences from the standing biomass at the initial period for a given age are the result of environmental changes. The arrows simply imply the direction of the changes and do not necessarily show a monotonic increase or decrease in biomass density; it might increase for a time then decrease, or it might vary back and forth. (Right) Corresponding with Left, environmental change may lead to (A) an increase, (B) no change, or (C) a decrease in biomass density of a forest type across all age classes in a certain inventory period. The shaded bands represent the fluctuations in growth in different age classes.

(BEF) (Table S1 and Materials and Methods), we distinguish the relative contribution and its regional variation of tree regrowth and growth enhancement to biomass C accumulation for major planted forest types in Japan from 1980 to 2005.

The reasoning is that forest types of the same age class and with similar management regimes across different inventory periods should have a similar biomass density (biomass per area) under equilibrium environmental conditions (i.e., atmospheric CO<sub>2</sub> concentration, N deposition, and climate). Thus, if the biomass density of forests of the same age class varies through time (or across different inventory periods), then the variation, either increasing or decreasing biomass density, should be induced by environmental changes (Fig. 1). We can assess the impact of environmental changes on forest growth by examining differences in forest biomass density for the same age class but over different inventory periods.

Considering that natural forests have multiple dominant tree species of different ages, here we focused on four major plantations in the country: Japanese cedar (*Cryptomeria japonica*), Japanese cypress (*Chamaecyparis obtusa*), Japanese red pine (*Pinus densiflora*), and Japanese larch (*Larix leptolepis*) plantations. To address regional differences in the response of forest growth to environmental change, following the forest inventory (25), we divided the country into eight regions: Hokkaido, Tohoku,

Kanto, Chubu, Kinki, Chugoku, Shikoku, and Kyushu-Okinawa (Materials and Methods).

## Results

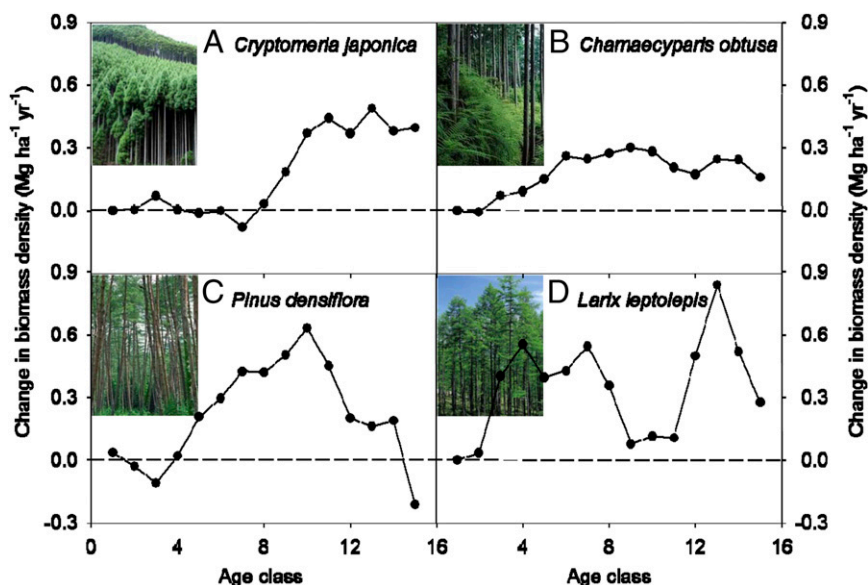

**Biomass C Accumulation.** Biomass density in all four planted forest types had significantly increased from 1980 to 2005 (Table 1; for more details, see Tables S2–S5). This growth was partitioned between two processes: age-related tree growth and environmentally induced enhancement. Japanese cedar plantation increased from 42.0 to 89.5 Mg C·ha<sup>-1</sup> (1 Mg = 10<sup>6</sup> g), Japanese cypress from 40.1 to 77.2 Mg C·ha<sup>-1</sup>, Japanese red pine from 29.2 to 58.3 Mg C·ha<sup>-1</sup>, and Japanese larch from 34.2 to 69.9 Mg C·ha<sup>-1</sup>, with a net increase of 47.5, 37.1, 38.3, and 35.7 Mg C·ha<sup>-1</sup>, respectively. As a result, total biomass C stock showed a large net gain of 212.4, 112.1, 23.9, and 32.9 Tg C (1 Tg = 10<sup>12</sup> g) for cedar, cypress, red pine, and larch forests, respectively.

**Environmentally Enhanced Growth and Its Contribution to Forest C Accumulation.** The changes in biomass density of a forest type at a given age class, except young forests, exhibited substantial increases over the inventory periods from 1980 to 2005 (Fig. 2), suggesting that tree growth in Japan has been enhanced by environmental changes for most stands of the plantations. This enhanced growth was largely age dependent within a certain forest type, although the ages most sensitive to enhanced growth varied among forest types. For Japanese cedar forests (Fig. 2A), there was no environmentally enhanced growth before the eighth age class (or 40 y old); that is, annual mean growth enhancement per area for an age class ( $GEPA_i$ ; for the details, see Materials and Methods) was about zero, then increased rapidly and remained at a value of 0.3–0.5 Mg C·ha<sup>-1</sup>·y<sup>-1</sup>. For Japanese cypress forests (Fig. 2B), the annual mean  $GEPA_i$  was small, about 0.3 Mg C·ha<sup>-1</sup>·y<sup>-1</sup> after the fifth age class (25 y old). For red pine forests (Fig. 2C), the annual mean  $GEPA_i$  did not change significantly at ages <20 y (the fourth age class), reached a maximum (0.63 Mg C·ha<sup>-1</sup>·y<sup>-1</sup>) at the 10th age class (50 y old), and then declined. For larch forests (Fig. 2D), the annual mean  $GEPA_i$  increased rapidly after the third age class and peaked (0.84 Mg C·ha<sup>-1</sup>·y<sup>-1</sup>) at the 13th age class (65 y old), but had small values (0.08–0.12 Mg C·ha<sup>-1</sup>·y<sup>-1</sup>) between the ninth and 11th age classes.

The growth enhancement varied widely among forest types. The highest rate of growth enhancement was observed in larch forests, with an average growth enhancement per area ( $GEPA$ ) of 7.7 Mg C·ha<sup>-1</sup> across all age classes over the period 1980–2005; that in other forest types showed a small range of 4.0–4.8 Mg C·ha<sup>-1</sup> (Table 2 and Table S6). The relative contribution of the growth enhancement to the total increase in biomass density ( $R_{gepa}$ ) showed the same order: the largest in larch forests (21.6%) and the smallest in cedar plantation (8.4%), suggesting a large

**Table 1.** Forest area, total biomass stock, and biomass density in different periods for four major planted forest types in Japan

Forest type	Item	Year						Change over 1980–2005
		1980	1985	1990	1995	2000	2005

**Fig. 2.** Environmentally induced annual changes in biomass density (biomass per area) with various age classes for four major plantations in Japan during the period 1980–2005. The numbers are obtained from annual mean *GEPA*, for each age class (Eq. 6 in *Materials and Methods*). Each age class represents 5 y. Minus or plus value shows negative or positive effects of environmental changes on forest growth. (A) Japanese cedar, (B) Japanese cypress, (C) Japanese red pine, and (D) Japanese larch plantations.

difference in the contribution of environmental enhancement to forest growth among various forest types (for details on *GEPA* and  $R_{gepa}$ , see *Materials and Methods*).

Using these rates and the total area of each forest type, we estimated total growth enhancement (TGE) and its contribution to total forest C accumulation across the country. The cypress and larch forests presented a similar, large TGE value (11.6 and 11.4 Tg C, respectively), and the other two forest types (cedar and red pine forests) showed a similar, small TGE (8.7 and 8.5 Tg C) (Table 2). Overall, the relative contribution ( $R_{ge}$ ) of TGE to total biomass C accumulation [net biomass increase (NBI)] was largest in red pine forests (35.5%), with a similar value in larch forest (34.7%), and smallest in cedar forest (only 4.1%) (for details on TGE and  $R_{ge}$ , see *Materials and Methods*).

**Regional Patterns of Growth Enhancement.** Although environmental changes have stimulated tree growth at the national scale, there were large regional differences in this enhancement (Fig. 3 and Table S6). For example, environmental changes stimulated the growth of red pine forest in northern regions (i.e., Tohoku, Kanto, Chubu, and Kinki) but inhibited its growth in southern areas (i.e., Shikoku, Chugoku, and Kyushu-Okinawa) (Fig. 3C), probably as the result of increased damage by disease and insect outbreaks under warmer and more humid environments in southern regions (25). Similarly, the contribution of growth enhancement to biomass C accumulation in larch forest tended to decrease from north to south, with more than 50% of  $R_{gepa}$  in Hokkaido and about 10% in Chubu (Fig. 3D). Regional distribution of the effects of environmental changes on total tree growth ( $R_{ge}$ ) showed patterns similar to those of  $R_{gepa}$  (Fig. S1), although there were greater variations in the former because of differences in forest area in different regions.

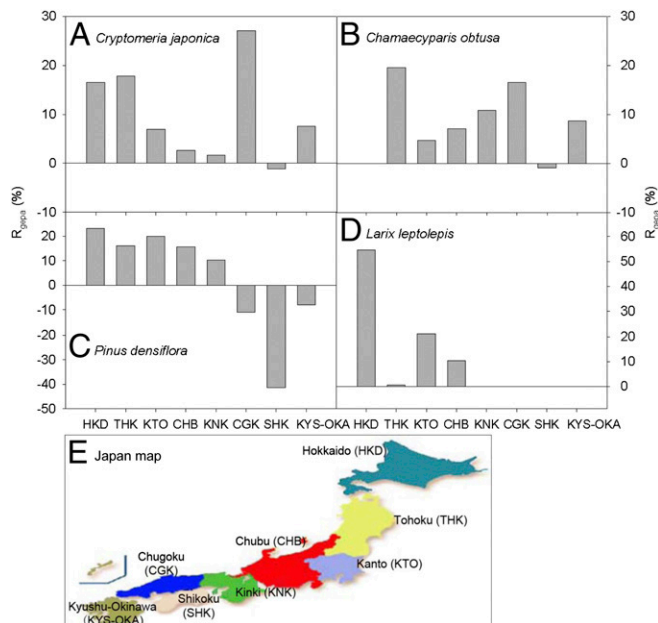

## Discussion

This analysis is, to our knowledge, the first to distinguish the relative contribution of age-related tree regrowth and environmentally enhanced growth to biomass C accumulation at a large scale. Our results demonstrate that age-related tree regrowth was the principle mechanism responsible for biomass C uptake in Japan's major plantations but that environmentally induced growth enhancement also made a substantial contribution to C sequestration. As indicated in Table 2, the four plantations sequestered environmentally enhanced C of 4.0–7.7 Mg·ha<sup>-1</sup> over 25 y (1980–2005). If we assume the estimates are average enhancement rates for the northern forests in the middle and high latitudes and simply translate these rates into the northern forests (a total area of  $1,780 \times 10^6$  ha; see ref 27), then these forests sequestered a total of 7.1–13.7 Pg C over the period 1980–2005, or 0.28–0.55 Pg C per year ( $1 \text{ Pg} = 10^{15} \text{ g}$ ). This is a substantial amount relative to a total C sink of 1.2 Pg·y<sup>-1</sup> for the world's boreal and temperate forests (3), demonstrating the importance of environmentally enhanced forest growth in mitigating the rise in atmospheric CO<sub>2</sub> concentration and global warming (13). However, as shown in Figs. 2 and 3, the fraction of C accumulation due to growth enhancement differed by forest type, forest age, and region. The overall fraction was estimated at 8.4–21.6% per hectare and 4.1–35.5% for the country total for the four plantations (Table 2 and Table S6).

What environmental changes explain this observed growth enhancement? To explore this issue, we compared the temporal changes in biomass density for given age classes over different inventory periods for each forest type (Fig. 4A) with the temporal trends in environmental factors (CO<sub>2</sub>, N deposition, and climate) over the country during 1980–2005 (Fig. 4B). As noted, the changes in biomass density increased significantly from 1980 to 2005 for all four forest types ( $P < 0.05$ ; Fig. 4A). Further,

**Table 2.** Country total contribution of environmentally enhanced growth to biomass carbon accumulation for four major plantations in Japan during 1980–2005

Forest type	NBIPA, Mg C·ha <sup>-1</sup>	GEPA, Mg C·ha <sup>-1</sup>	$R_{gepa}$ , %	NBI, Tg C	TGE, Tg C	$R_{ge}$ , %
<i>C. japonica</i>	47.5	4.0	8.4	212.3	8.7	4.1
<i>C. obtusa</i>	37.1	4.1	11.0	112.0	11.6	10.4
<i>P. densiflora</i>	38.3	4.8	12.6	23.9	8.5	35.5
<i>L. leptolepis</i>	35.7	7.7	21.6	32.9	11.4	34.7

**Fig. 3.** Regional differences in environmentally induced growth for four major plantations in Japan, described as the contribution of growth enhancement per hectare to the total increase in biomass density ( $R_{ypm}$ ). (A) Japanese cedar, (B) Japanese cypress, (C) Japanese red pine, (D) Japanese larch plantations, and (E) map of Japan showing the regional divisions used in this study. Following Japanese inventories, the country was divided into eight regions: Hokkaido (HKD), Tohoku (THK), Kanto (KTO), Chubu (CHB), Kinki (KNK), Chugoku (CGK), Shikoku (SHK), and Kyushu-Okinawa (KYS-OKA).

Japan has experienced dramatic environmental changes during the past decades, with a continuous increase in atmospheric  $\text{CO}_2$  concentration, a significantly warming climate, and substantial N input into land ecosystems (Fig. 4B); that is, there are strong agreements between the biomass change and environmental trends over the study period for each forest type. A general linear model (GLM) analysis suggests that the four environmental variables explain >99% of the variations in enhanced growth for all four forest types, with elevated  $\text{CO}_2$  explaining the largest proportion of the variations (Table 3).

The results suggest that all the environmental changes stimulated tree growth over the study period, consistent with other findings. Elevated  $\text{CO}_2$  concentrations cause C fertilization of trees (28, 29), and natural N deposition increases soil N availability and plant N uptake and thus stimulates vegetation growth (30, 31). In addition, Japan is under an oceanic humid climate (32), and therefore warming climate can stimulate biomass C accumulation either through its direct effects on increased rates of photosynthesis and longer growing seasons or through indirect effects on increased nutrient availability due to increased rates of litter decomposition and N mineralization (33).

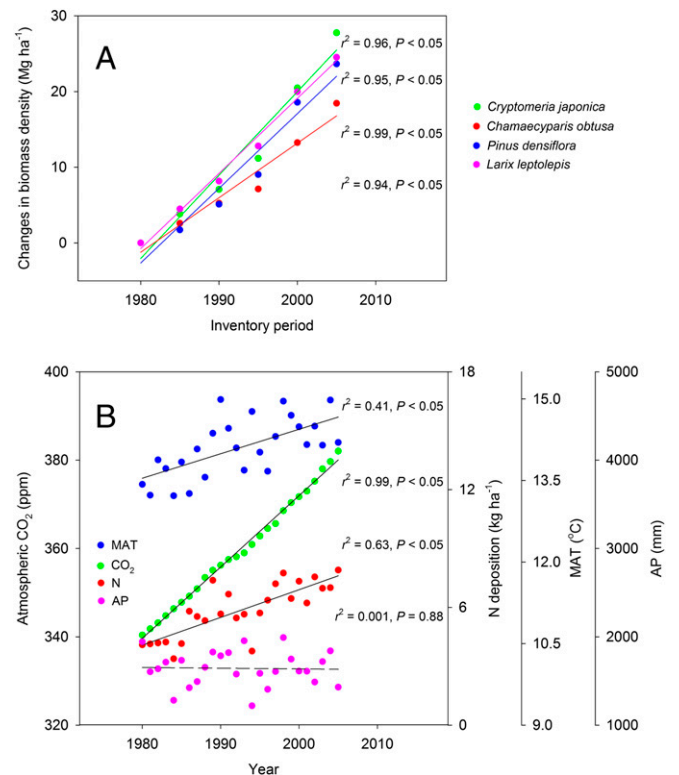

Our approach is sensitive to changes in management practices, but although practices may have varied locally, they should not have exerted substantial effects on the national-scale analysis. Moreover, national forestry management policies and regimes have not changed substantially over the past several decades in the country (34). For example, there were no significant changes in standing biomass at young-age classes over the different inventory periods (Table S7), suggesting similar silvicultural treatments (e.g., planting density and nurturing); management practices for stand density were similar throughout stand development (Ishikawa Agriculture and Forestry Research Center; <http://www.pref.ishikawa.lg.jp/ringyo/>); and commercial harvests did not vary over time, because most of the wood consumed in Japan

is imported (34). In addition, as shown in Fig. 4 and Table 3, a strong correlation ( $P < 0.001$ ) between increased biomass density and changes in environmental variables implies no significant effect of management on our analysis.

Our results have several implications. First, the significant contribution of environmentally enhanced growth to the forest biomass C sink emphasizes that C accumulation in forest ecosystems will not necessarily attenuate at a predictable rate as forests mature. Second, to reduce the uncertainties in predicting future C dynamics in forest ecosystems, land surface models should not only consider land-use history, but also account for key physiological processes governing the fate of C sequestration in forest ecosystems, such as the effects of  $\text{CO}_2$  fertilization, N deposition, and climate warming on vegetation growth. Third, the responses to environmental variability highlight that both stand age and tree traits regulate the sensitivity of the responses of forest growth to global environmental changes. These features should be incorporated into land surface models when predicting future forest C dynamics under a changing environment.

## Materials and Methods

**Forest Inventory Data.** In this study, forest inventory data were used to investigate the spatial-temporal pattern of forest growth and its response to

**Fig. 4.** Comparison between temporal changes in biomass density at given age classes and temporal trends in environmental variables over the study periods. (A) Changes in overall mean biomass density at 5–15 age classes over six inventory periods from 1980 to 2005 for all four forest types. Young age-class stands (fewer than five age classes) were excluded from this analysis because the numbers in initial growth stages are small and may not be influenced by environmental changes (Fig. 2). Biomass density at given age classes (i.e., age-excluded growth) exhibits a significant increase for all forest types. (B) Temporal trends in environmental variables ( $\text{CO}_2$  concentration, N deposition, MAT, and AP) over the whole country during 1980–2005. All variables except AP showed a significant increase over 25 y. Solid lines indicate a statistically significant increase at  $P < 0.05$ , and dashed lines reflect a nonsignificant change. For the data of environmental variables, see *Materials and Methods*.

**Table 3. Summary of the results obtained from a GLM showing the integrative effects of elevated CO<sub>2</sub>, N deposition, and climatic change on tree growth across different inventory periods for four major plantations in Japan**

Forest type	Result*	Environmental variable				Residuals
		CO <sub>2</sub>	N	MAT	AP

global environmental changes from 1980 to 2005. Japan has conducted a systematic forest inventory since the 1960s but has consistently reported area and volume of major forest types at each age class in each region (prefecture) only from 1980. In Japan's forest inventory program, there are 10,000 permanent plots (1,000 m<sup>2</sup>, 31.62 m × 31.62 m) with a 1-km × 1-km grid. The inventory provides information on forest ownership, tree species, age class, diameter at breast height, tree height, and volume. Forest is defined as an area with 20% or more crown cover for government-owned forests and more than 30% crown cover for community and privately owned forests. The error of timber volume at the country scale is less than 3% (25). According to the forest inventory, natural forests tend to have more tree species with different ages whereas plantations generally have only a few species of similar age. Therefore, this study focused on the biomass C sink and its driving environmental factors for Japan's plantations. The forest inventory recorded the area and volume of four coniferous plantations (*Cryptomeria japonica*, *Chamaecyparis obtusa*, *Pinus densiflora*, and *Larix leptolepis*) for each age class during 1980–2005. Among the four plantations, forest inventories reported the area and volume in each prefecture for every age class (i.e., 5, 10, 15, 20, and so on). Thus, the average volume of each age class in each prefecture, each region, and the whole country can be calculated for each of the six inventory periods (1980, 1985, 1990, 1995, 2000, and 2005).

**BEF and Biomass Estimation.** Given that forest inventory reports only timber volume rather than biomass of the whole forest, BEF is needed to convert volume into biomass. It has been shown that BEF may be expressed as a function of volume (24, 26, 35, 36). Using 942 sets of field measurement data on forest biomass and volume, Fang et al. (26) developed the functions for estimating BEF values for main forest types in Japan (Eq. 1 and Table S1). These functions are independent of stand density, age class, and site. These BEF values may be used for estimating living biomass of the stand, including leaves, fruits, branches, stems, and roots of all woody plants. Forest floor materials are not included in the BEF values because the available data are very scarce and highly variable among studies;

$$BEF = a + \frac{b}{x}, \quad [1]$$

where *x* is stand volume and *a* and *b* are regression coefficients. BEF approaches the constant *a* when stand volume increases.

Using Eq. 1, BEF can be applied to forest inventory data to estimate regional- or national-scale forest biomass (37). For a particular forest type, regional biomass can be estimated by the following equation:

$$Y = \sum_{i=1}^n A_i \cdot x_i \cdot BEF_i, \quad [2]$$

where *Y* is total biomass in a particular region and *A<sub>i</sub>*, *x<sub>i</sub>*, and *BEF<sub>i</sub>* are the total area, volume per unit area, and BEF value for prefecture *i* in this region.

**Estimation of National and Regional Total Biomass Across All Age Classes.** The national total biomass for a particular forest type was calculated using Eq. 3. Similarly, we can further calculate the national total biomass (*NB<sub>j</sub>*, Eq. 4) and its average biomass density (*BD<sub>j</sub>*, Eq. 5) for this forest type at age class *j*. The biomass density at each age class (*BD<sub>i</sub>*) in the whole country may be used further to compare growth differences among different age classes (Tables S2–S5). Likewise, the regional biomass density at each age class for a particular forest type can be calculated. In the forest inventory, Japan was divided into eight regions: Hokkaido, Tohoku, Kanto, Chubu, Kinki, Chugoku, Shikoku, and Kyushu-Okinawa. We calculated the biomass density at each age class in each region and compared growth differences among regions:

$$NB = \sum_{i=1}^m \sum_{j=1}^n A_{ij} \cdot x_{ij} \cdot BEF_{ij} \quad [3]$$

$$NB_j = \sum_{i=1}^m A_{ij} \cdot x_{ij} \cdot BEF_{ij} \quad [4]$$

$$BD_j = NB_j / A_j = \sum_{i=1}^m A_{ij} \cdot x_{ij} \cdot BEF_{ij} / \sum_{i=1}^m A_{ij}, \quad [5]$$

where *NB* is the total national biomass for a particular forest type during a specific inventory period; *A<sub>ij</sub>*, *x<sub>ij</sub>*, and *BEF<sub>ij</sub>* are area, volume per unit area, and BEF value of this forest type in prefecture *i* and at age class *j*; *n* is the number of age classes; *m* is the number of prefectures; and *A<sub>j</sub>* is the total area of the forest type at age class *j*.

**Calculation of Growth Enhancement Due to Environmental Changes.** At the national or regional scale, if a particular forest type has a similar management regime across different periods, is under relatively constant environmental conditions (i.e., atmospheric CO<sub>2</sub> concentration, N deposition, and climate), and appears to be at an equilibrium state, then the overall mean biomass density (*ρ*) of this forest at a particular age class but different periods should be constant (i.e., ∂*ρ*/∂*t* = 0). If *ρ* changes in different periods, it should be caused by environmental changes. In response to a changing environment, forest biomass density might increase, decrease, or keep relatively stable (no change) across different periods (for details, see legend of Fig. 1). We thus can assess the impact of environmental changes on forest biomass density (biomass per area) simply by investigating changes in biomass density at the same age class but over different inventory periods. If we conduct this analysis for all age classes, we can get environment-induced growth enhancement at different age classes.

The following equation was used to calculate the response of biomass density at a given age class to environmental factors during the study period (a total of six inventory periods during the 25 y from 1980 to 2005):

$$GEPA_i = \sum_{j=1}^5 (BD_{ij} - BD_{i(j-1)}), \quad [6]$$

where *GEPA<sub>i</sub>* (growth enhancement per area for an age class) is the environment-induced change in biomass density at age class *i* during the study period 1980–2005, indicating the magnitude of response of forest biomass density at age class *i* to environmental changes. *BD<sub>ij</sub>* is biomass density at age class *i* and in period *j*: when *i* is 1, 2, 3, ..., *n*, age is 5, 10, 15, ..., 5*n* accordingly; when *j* is 1, 2, 3, 4, and 5, the period is year 1985, 1990, 1995, 2000, and 2005, respectively. *BD<sub>i0</sub>* stands for biomass density at age class *i* and in the beginning year (1980) of the study period. Annual mean *GEPA<sub>i</sub>* (megagrams of C per hectare per year) in the main text (and Fig. 2) is calculated by dividing *GEPA<sub>i</sub>* by the length of the study periods (in most cases, 25 y in this study).

The age-class averaged growth enhancement per area (*GEPA*) during 1980–2005 thus can be expressed as

$$GEPA = \frac{1}{n} \sum_{i=1}^n GEPA_i = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^5 (BD_{ij} - BD_{i(j-1)}); \quad [7]$$

the TGE due to environmental changes for a particular forest type can be quantified further as

$$TGE = \sum_{i=1}^n \sum_{j=1}^5 \left( (BD_{ij} - BD_{i(j-1)}) \cdot \frac{1}{2} (A_{ij} + A_{i(j-1)}) \right), \quad [8]$$

where *BD<sub>ij</sub>* and *A<sub>ij</sub>* represent biomass density and area of this forest type at age class *i* and in inventory period *j*, respectively, whereas *BD<sub>i0</sub>* and *A<sub>i0</sub>*

stand for biomass density and forest area at age class  $i$  and in year 1980, respectively.

**Estimation of Relative Contribution of Environmental Changes.** The relative contribution of environmental changes to total forest biomass C sink ( $R_{ge}$ , %) was calculated as the ratio of environment-induced TGE to total NBI during the inventory period. In addition, the relative contribution of environmental changes to growth enhancement per area ( $R_{gepa}$ , %) was determined as the ratio of environment-induced GEPA to average net biomass increase per area across all age classes (NBIPA) during the inventory period:

$$NBI = NB_{2005} - NB_{1980} \quad [9]$$

$$R_{ge} = TGE/NBI \times 100\% \quad [10]$$

$$NBIPA = BD_{2005} - BD_{1980} \quad [11]$$

$$R_{gepa} = GEPA/NBIPA \times 100\% \quad [12]$$

where  $NB_{1980}$  and  $NB_{2005}$  represent total biomass of this forest type in years 1980 and 2005, respectively, and  $BD_{1980}$  and  $BD_{2005}$  are biomass density in years 1980 and 2005, respectively.

**Data of Environmental Variables.** In this study, we used four environmental variables: mean annual temperature (MAT), annual precipitation (AP), atmospheric CO<sub>2</sub> concentration, and N deposition. MAT and AP during the period

1980–2005 were averaged from 138 climatic stations across the country (Japan Meteorological Agency; [http://ds.data.jma.go.jp/ghg/kanshi/ghgp/co2\\_e.html](http://ds.data.jma.go.jp/ghg/kanshi/ghgp/co2_e.html)). Annual CO<sub>2</sub> concentrations for 1987–2005 were averaged from three stations in Japan (Ryori, Minamitorishima, and Yonagunijima) (Japan Meteorological Agency; <http://ds.data.jma.go.jp/abd/stats/data/en/smp/index.html>). The CO<sub>2</sub> concentrations were extended back to 1980 by regressing the Mauna Loa CO<sub>2</sub> data against each of the three stations (Pearson's  $r^2$ : 0.9995, 0.9994, and 0.9993 for Ryori, Minamitorishima, and Yonagunijima, respectively). For wet N deposition, we used a nationwide monitoring database (Japan Acid Deposition System) that was started in 1983 (38). Mean annual wet N deposition data across the country were derived from all available observations.

**Statistical Analysis.** We performed ordinary least squares regression to examine temporal changes in biomass density in the four major plantations among different inventory periods, as well as temporal variability in environmental variables across the country during the period 1980–2005. We then conducted a GLM analysis to evaluate their comprehensive effects on biomass changes over different inventory periods. All statistical analyses were conducted using SPSS 13.0 (39).

**ACKNOWLEDGMENTS.** We thank L. Y. Chen for preparing Fig. 1 and two anonymous reviewers for helpful comments on a previous version of the manuscript.
