Over the past decade, the research agenda in dialysis has been dominated by studies on risk factors associated with cardiovascular mortality. It has now become increasingly clear that in dialysis patients, non-cardiovascular causes of death are increased to the same extent as cardiovascular mortality, and therefore research efforts in this area deserve an equally prominent place on the nephrology research agenda. As previous research has suggested an association between cardiovascular disease and infections, more research on potential links between the causal pathways of cardiovascular events and infections is also warranted.

Jager KJ, Lindholm B, Goldsmith D *et al.* Cardiovascular and non-cardiovascular mortality in dialysis patients: where is the link? *Kidney Int Sup* 2011; **1**: 21–23.

More than a decade ago, Foley *et al.*¹ had studied a USRDS data set including patients with end-stage renal disease (ESRD), and after stratification for age, race, and sex they found mortality from cardiovascular disease to be 10–20 times higher in ESRD patients compared with the general population. This study has been cited more than 800 times, frequently to justify studies pertaining to the effect of cardiovascular risk factors on mortality in chronic kidney disease (CKD) patients. Even more common, this reference has been used to underline the fact that cardiovascular disease, which is responsible for around half of the deaths in dialysis patients, is the most important cause of death in this population. Finally, the findings of the study by Foley *et al.* have not only been used to justify specific studies, but they have also to a large extent set the research agenda for CKD since their publication in 1998.

Although it has been established beyond any doubt that cardiovascular events are an important cause of death in CKD patients, this is only half the truth. Cardiovascular mortality is also important in the general population. Depending on the age category, it is responsible for 10–50% of mortality in the general population, whereas in dialysis patients these percentages are 20–40.² Therefore, the fraction of cardiovascular deaths is quite similar in both populations. From this perspective, the findings of Foley *et al.* can only be understood if in dialysis patients mortality due to non-cardiovascular disease is increased to the same extent as mortality from cardiovascular causes. Indeed, results from other studies conducted on the same USRDS data set have

shown that, in dialysis patients, mortality from sepsis is 50 times higher³ and that from pulmonary infections is 14–16 times higher⁴ compared with the general population. However, these findings have received very little attention compared with those showing increased cardiovascular mortality. More recently, de Jager *et al.*² analyzed data from the European Renal Association–European Dialysis and Transplant Association (ERA–EDTA) Registry and not only confirmed the findings of Foley and colleagues but also showed that in dialysis patients mortality from non-cardiovascular disease was increased to the same extent as mortality from cardiovascular disease. Taking the general population in Europe as a reference, the age-adjusted cardiovascular mortality in dialysis patients was 8.8 times higher, whereas the non-cardiovascular mortality was increased 8.1 times.² To add to this perspective, it is interesting to note that the increased risk of both cardiovascular and non-cardiovascular mortality in dialysis patients is complemented by the observation that, in elderly individuals with a more advanced stage of CKD, the age- and sex-adjusted risk of death from non-cardiovascular causes is increased compared with those with better renal function.⁵ Apparently, individuals with CKD die prematurely from all kinds of causes compared with individuals of the same age in the general population. We recently presented clinical and experimental data showing that the cardiovascular events associated with atherosclerosis are more often fatal in patients with CKD than in individuals without CKD.⁶

The studies on ERA–EDTA Registry and USRDS data in dialysis patients^{2–4} are particularly worrisome, as their results do not seem to fit well with the commonly held opinion that, in order to reduce the highly increased mortality in these patients, we should predominantly study and decrease traditional and non-traditional cardiovascular risk factors. On the other hand, from these studies it cannot be concluded that investigating and treating cardiovascular risk factors in CKD patients would not be helpful. We would simply like to argue that reduction of cardiovascular and non-cardiovascular mortality deserves equal attention.

Our understanding is further hampered by the publication in the past few years of a number of ‘negative trials’, randomized controlled trials (RCTs) that failed to show a beneficial effect of interventions aimed at decreasing cardiovascular risk factors, although such interventions have established positive effects on mortality in the general population. For instance, cardiovascular end points including cardiovascular mortality were not reduced in CKD or dialysis patients in published RCTs in which they attempted to correct, for example, hypercholesterolemia^{7,8} or anemia.^{9,10}

Given these findings from epidemiological and intervention studies, three questions arise:

- (1) Why are both cardiovascular and non-cardiovascular mortality rates increased to the same extent?
- (2) What are the effects of cardiovascular disease on non-cardiovascular events and vice versa? and

- (3) Why does treatment of established cardiovascular risk factors not seem to decrease cardiovascular mortality in dialysis patients?

In relation to the first question, it is common knowledge that non-cardiovascular causes of death, such as malignancy, share a number of risk factors with cardiovascular mortality—for example, smoking, obesity, physical inactivity, and diet. The prevalence of some of those factors is increased in CKD patients, as they are also risk factors for CKD itself. On the contrary, cancer itself, as well as the adverse effects of therapies for cancer, can directly or indirectly cause CKD.¹¹ Also related to the first question, both cardiovascular and infectious causes of death are linked to inflammation and it has become increasingly appreciated that ESRD is characterized by a state of chronic inflammation.¹² There is a wealth of evidence indicating that disorders of both innate and adaptive immune systems contribute to an increased rate of infections in the course of ESRD.¹³ Although defensive responses are impaired, the immune system is also under constant stimulation because of the process of dialysis itself.¹⁴

With regard to the second question, it has been shown that infections and cardiovascular events are interrelated. In individuals under the care of a general practitioner, the risk of myocardial infarction and that of stroke were substantially higher after a diagnosis of systemic respiratory tract infection, especially during the first 3 days of infection.¹⁵ This supports the concept that acute infections are associated with a transient increase in the risk of vascular events.¹⁵ Furthermore, Ishani *et al.*¹⁶ showed that in dialysis patients septicemia or bacteremia was associated with subsequent death, myocardial infarction, heart failure, peripheral vascular disease, and stroke. They concluded that septicemia appears to be an important, potentially preventable, cardiovascular risk factor in this patient group. Conversely, particular cardiovascular diseases such as heart failure and volume overload may elicit conditions favorable for the development of infections. In this context, it is interesting that in ESRD patients volume overload is one of the putative causes of elevated circulating TNF- α levels.¹⁴ Thus, infections are associated with subsequent cardiovascular events, and particular cardiovascular disorders may elicit infections. It is possible that these problems may aggravate each other. Therefore, other potential causal pathways in the link between non-cardiovascular and cardiovascular diseases and their potential common causes (including the role of the immune system) also need to be studied further. Hypotheses in this area need to be tested in animal models and laboratory experiments.

An answer is also much needed for the third question. RCTs in CKD to date have studied interventions that in the general population have been shown primarily to reduce death from myocardial infarction or stroke. However, in dialysis patients, an important part of the cardiovascular deaths can be attributed to other “competing” causes of death,¹⁷ such as sudden death, which may not be modifiable by interventions aimed to reduce hypercholesterolemia or

1. To hypothesize and investigate potential mechanisms for increased non-cardiovascular mortality in chronic kidney disease (CKD)/dialysis patients, including infections and malignancies.
2. To study the link between cardiovascular and non-cardiovascular events and to investigate potential common causes.
3. To test hypotheses in animal models and laboratory experiments.
4. Thereafter, to study the effect of markers and modifiable risk factors in carefully designed observational studies in the CKD/dialysis population.
5. To test the effects of smart interventions in randomized controlled trials.
6. To include risk factors for sudden death, and related potential interventions, into the studies on cardiovascular mortality in this population.

Figure 1 | Proposal for a new research agenda on the cardiovascular-renal and non-cardiovascular-renal links.

anemia. In addition, dialysis patients comprise a highly selected population.¹⁷ It is therefore possible that in these RCTs interventions were tested that are relatively ineffective in the reduction of total mortality in this particular patient population. Studies on (addressing) risk factors for sudden death are warranted.

In conclusion, the research agenda for the reduction of mortality in dialysis patients (Figure 1) should focus on both cardiovascular and non-cardiovascular causes of death. In addition, research in cardiovascular mortality may better differentiate between the effects of interventions aimed to reduce specific types of cardiovascular mortality. Finally, the potential link between cardiovascular and non-cardiovascular mortality deserves further investigation.
