**Background:** Colorectal cancer peritoneal metastasis (CPM) confers an exceptionally poor prognosis, and traditional treatment involving systemic chemotherapy (SC) is largely ineffective. Cytoreductive surgery (CRS) combined with hyperthermic intraperitoneal chemotherapy (HIPEC) is increasingly advocated for selected patients with CPM; however, opinions are divided because of the perceived lack of evidence, high morbidity, mortality, and associated costs for this approach. As there is no clear consensus, the aim of this study was to compare outcomes following CRS + HIPEC vs SC alone for CPM using meta-analytical methodology, focusing on survival outcomes. Secondary outcomes assessed included morbidity, mortality, quality of life (QOL), and health economics (HE).

**Methods:** An electronic literature search was conducted to identify studies comparing survival following CRS + HIPEC vs SC for CPM. The odds ratio (OR) was calculated using the Mantel–Haenszel method with corresponding 95% confidence intervals (CI) and *P*-values. Heterogeneity was examined using the *Q*-statistic and quantified with *I*<sup>2</sup>. The fixed-effect model (FEM) was used in the absence of significant heterogeneity. For included studies, 2- and 5-year survival was compared for CRS + HIPEC vs SC alone.

**Results:** Four studies (three case–control, one RCT) provided comparative survival data for patients undergoing CRS + HIPEC (*n* = 187) vs SC (*n* = 155) for CPM. Pooled analysis demonstrated superior 2-year (OR 2.78; 95% CI 1.72–4.51; *P* = 0.001) and 5-year (OR 4.07; 95% CI 2.17–7.64; *P* = 0.001) survival with CRS + HIPEC compared with SC. Mortality ranged from 0 to 8%. No data were available for the assessment of QOL or HE.

**Conclusions:** Although limited by between-study heterogeneity, the data support the assertion that in carefully selected patients, multimodal treatment of CPM with CRS + HIPEC has a highly positive prognostic impact on medium- and long-term survival compared with SC alone. There is a paucity of comparative data available on morbidity, QOL, and HE.

Colorectal carcinoma (CRC) is a key public health issue and accounts for the second highest cause of cancer-related death in Europe (Ferlay *et al*, 2013). Metastases are the principal causes of death and occur in 30% of patients at presentation (Cunningham *et al*, 2010) and subsequently in over 50% following surgery with curative intent (Cunningham *et al*, 2010). Although historically the presence of metastases has been regarded with pessimism and as a symbol of incurability, the last three decades have seen remarkable advances in the multimodality management of metastatic CRC, with combinations of neoadjuvant and adjuvant chemotherapy regimens (Cunningham *et al*, 2004), radiotherapy (Lee *et al*, 2013), and radical surgery (van Dijk *et al*, 2013; Yi *et al*, 2013) increasingly deployed to combat metastases. These approaches have led to improved oncological outcomes in selected patients, and even long-term survivorship notwithstanding distant spread. Despite a paucity of high-quality randomised studies to direct this shift, the dramatic results seen with these pragmatic approaches have been persuasive, and multimodality treatment of liver and lung metastases is now the standard of care in many institutions (Tampellini *et al*, 2012; Nordlinger *et al*, 2013).

One area of contention in the management of metastases from CRC has been the treatment of peritoneal metastases. Approximately 5–10% of patients undergoing CRC resection are found to have synchronous peritoneal metastases (Chu *et al*, 1989; Sadeghi *et al*, 2000; Jayne *et al*, 2002), whereas a further 20–50% go on to experience metachronous intraperitoneal recurrence (Sadeghi *et al*, 2000). Conventional treatment of colorectal cancer peritoneal metastasis (CPM) involving systemic chemotherapy (SC), with or without palliative surgery, has a poor outlook with a median survival of 5–7 months (Chu *et al*, 1989; Sadeghi *et al*, 2000; Jayne *et al*, 2002). In more recent times, however, a radical multimodality locoregional approach combining cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) has been advocated as a treatment option and is offered in a growing number of specialist units (Glehen *et al*, 2010; Kuijpers *et al*, 2013; Riss *et al*, 2013). The aim of this approach is to remove all macroscopic disease through peritoneal stripping and multivisceral resections where required, followed by administering hyperthermic chemotherapy intraoperatively into the abdomen to treat residual microscopic disease. This method achieves high intraperitoneal concentrations of cytotoxic drugs, avoids significant systemic absorption, and additionally offers a synergistic cytotoxic effect from the combination of hyperthermia and chemotherapy (Brucher *et al*, 2012).

Support for this approach has been largely based on a small number of studies showing improved survival outcomes with CRS and HIPEC compared with SC alone (Verwaal *et al*, 2008; Elias *et al*, 2009). Despite these encouraging reports, the relative lack of level-1 evidence and concerns with respect to peri-operative morbidity, mortality, and health-care costs has divided opinion regarding these aggressive multimodality approaches, and the optimal management of CPM, therefore, remains controversial (Khatri, 2010).

The present study provides a meta-analytical evaluation of survival outcomes with CRS combined with HIPEC (CRS + HIPEC) compared with SC alone. To our knowledge, this is the first pooled analysis to have synthesised data from multiple studies assessing the role of CRS and HIPEC, specifically in the context of CPM.

## MATERIALS AND METHODS

**Identification of studies.** An electronic literature search was carried out using MEDLINE (1965–September 2013), EMBASE (1980–September 2013), CINAHL (1982–September 2013), and the Cochrane Library databases. The following medical subject heading terms and key words were used: ‘colorectal cancer’;

‘peritoneal’; ‘carcinomatosis’; ‘cytoreductive surgery’; ‘chemotherapy’; ‘intraoperative’; and ‘intraperitoneal’. The ‘related articles’ function was used to broaden the search and all abstracts, studies and citations retrieved were scanned for subject relevance. The latest date of this search was January 2014. All potentially relevant publications were retrieved in full text and formally evaluated for study inclusion. Reference lists of all relevant publications were hand-searched for additional studies missed by the search strategy, and this method of cross-referencing was continued until no further relevant publications were identified.

**Study inclusion criteria and data extraction.** Study methodology was carried out in accordance with the ‘Preferred Reporting Items for Systematic Reviews and Meta-Analyses’ (PRISMA) recommendations for improving the standard of systematic reviews (Moher *et al*, 2009). Included studies had to provide comparative survival outcome data in  $\geq 15$  male/female adult patients ( $\geq 18$  years) with a histologically confirmed diagnosis of primary or recurrent CPM undergoing treatment with either CRS + HIPEC or SC alone. Studies reporting comparative outcomes for cancer subtypes other than colorectal were only included if survival outcome data were reported independently for CPM cases. Only English language publications were included. Two reviewers (RM and AHM) independently extracted the following data from all eligible studies according to a predetermined protocol: First author, year of publication, study location, study type, study time frame, population characteristics, number of subjects, primary or recurrent disease, stage of CPM (peritoneal cancer index (PCI; Jacquet and Sugarbaker, 1996) or alternative scoring method for disease extent), chemotherapeutic regimen, details of previous treatment (chemotherapy/radiotherapy), follow-up duration, incidence of morbidity and mortality, completeness of cytoreduction (CCR, CCR score (Sugarbaker, 1999) and/or R-classification where reported), and 2- and 5-year survival (overall and/or disease-free). In cases of doubt, authors were contacted for further information to ensure accuracy. Where actuarial survival outcomes were not reported for 2 and 5 years specifically, and authors could not be contacted, data were digitally extracted from Kaplan–Meier survival plots using graphic digitisation software (DigitizeIt, Braunschweig, Germany) according to previously published methodology (Guyot *et al*, 2012). Data from studies including mucinous appendiceal tumours were excluded, unless the data were separately evaluable. Extracted data were entered into a computerised database and cross-checked to reach consensus. Included studies were subjected to an assessment of methodological quality and validity and graded on strength of evidence using the revised grading system of the Scottish Intercollegiate Guidelines Network (Harbour and Miller, 2001).

**Statistical analysis.** Statistical analysis was performed using Comprehensive Meta-analysis Version 2, Biostat (Englewood, NJ, USA) to derive odds ratios (ORs) with corresponding 95% confidence intervals (CIs) for 2- and 5-year survival with CRS + HIPEC *vs* SC alone. Between-study heterogeneity was assessed using Cochran’s *Q*-test and further quantified using the  $I^2$  statistic. The *Q*-statistic is underpowered and therefore homogeneity of studies was assumed at a *P*-value greater than 0.1 (Song *et al*, 2001). The  $I^2$  statistic is derived independently of the number of studies and indicates low heterogeneity at or below 25% (Higgins and Thompson, 2002; Higgins *et al*, 2003). Overall pooled OR for 2- and 5-year survival with 95% CI was calculated using the fixed-effect model (FEM), in the absence of significant study heterogeneity. The relative weight conferred to each study is inversely proportional to the variance associated with the OR and is represented by squares in the forest plots. The pooled estimate is represented by a diamond in the forest plots, the width of which corresponds to the 95% CI. Publication bias was assessed visually with funnel plots and Egger’s regression test (Egger *et al*, 1997;

Sutton *et al*, 2000). No significant publication bias was assumed if the 95% CI included 0.

## RESULTS

**Literature search and description of studies.** Our predefined search strategy identified a total of 265 potentially relevant publications. Following screening of titles and abstracts, 175 articles were excluded, leaving 90 publications that were retrieved in full text. A bibliographic search from these articles identified three additional studies providing a total of 93 articles for detailed evaluation. Of these, 89 were subsequently withdrawn leaving a total of four studies published between 2004 and 2010 that were entered into the review process. Figure 1 provides a summary of the outlined search strategy.

Three case-control studies (Mahteme *et al*, 2004; Elias *et al*, 2009; Franko *et al*, 2010) (evidence level 2-) and one RCT (Verwaal *et al*, 2008; evidence level 1-) published between 2004 and 2010 met our inclusion criteria and were included in the meta-analysis. The included studies comprised a total of 342 patients with CPM, of whom 187 were treated with CRS + HIPEC and 155 received standard treatment with SC alone. Table 1 provides a summary of study design and treatment protocols for included studies. In three of the studies HIPEC was administered intraoperatively, commencing immediately after CRS (Verwaal *et al*, 2008; Elias *et al*, 2009; Franko *et al*, 2010) with duration of treatment ranging from 30 to 100 min. In one study, intraperitoneal chemotherapy was administered from the first postoperative day onwards (early postoperative intraperitoneal chemotherapy, EPIC) for a variable duration (Mahteme *et al*, 2004). The intraperitoneal chemotherapeutic agent was mitomycin C (MMC) in two of the studies (Verwaal *et al*, 2008; Franko *et al*, 2010). Elias *et al* (2009) used a bidirectional protocol consisting of intraperitoneal Oxaliplatin and intravenous 5-fluorouracil (5-FU) and Leucovorin. Mahteme *et al* (2004) administered IV Leucovorin 60 min into the initiation of intraperitoneal chemotherapy with 5-FU. In the study by Verwaal *et al* (2008) 105 patients with CPM were randomised to SC alone

(5-FU + Leucovorin;  $n = 51$ ) or CRS + HIPEC (MMC;  $n = 54$ ) treatment arms. Importantly, all patients in the CRS + HIPEC group received adjuvant chemotherapy (5-FU + Leucovorin). The study by Elias *et al* (2009) compared outcomes following CRS + HIPEC ( $n = 48$ ) and SC alone for treatment of CPM. All patients in the CRS + HIPEC treatment arm received neoadjuvant (NA) chemotherapy, and only patients who demonstrated no evidence of disease progression after 3–4 months of NA therapy were included.

**Patient selection.** The primary indication for treatment was defined as the presence of peritoneal metastases of colorectal origin in all four of the studies included. Age as a means of patient selection was restricted to <75 years (Mahteme *et al*, 2004), <71 years (Verwaal *et al*, 2008), and <66 years (Elias *et al*, 2009) in different studies. Patients with 'extensive' and/or 'significantly symptomatic' CPM were deemed ineligible for study enrolment in two of the studies (Mahteme *et al*, 2004; Elias *et al*, 2009). More precise definitions were not provided with respect to assessment of resectability in these two studies. Patients with lung/liver metastases or other extra-abdominal disease were excluded in two studies (Mahteme *et al*, 2004; Verwaal *et al*, 2008), whereas two studies included patients with limited liver metastases (Elias *et al*, 2009; Franko *et al*, 2010). Three of the studies only included patients deemed to be of good general functional status (Mahteme *et al*, 2004; Verwaal *et al*, 2008; Elias *et al*, 2009). This classification was further defined in only two of the studies, with normal bone marrow indices and renal and liver function tests regarded as components of the eligibility criteria for one study, whereas an American Society of Anaesthesiology score of 1 or 2 was regarded as inclusion criteria for another of the studies included in this meta-analysis (Mahteme *et al*, 2004; Verwaal *et al*, 2008). Study recruitment was restricted to patients aged <75 years (Mahteme *et al*, 2004), <71 years (Verwaal *et al*, 2008), and <66 years (Elias *et al*, 2009) in different studies.

**Survival.** Survival outcome data are summarised in Table 2. Mahteme *et al* (2004) reported vastly superior 2- and 5-year survival following CRS + HIPEC compared with SC alone.

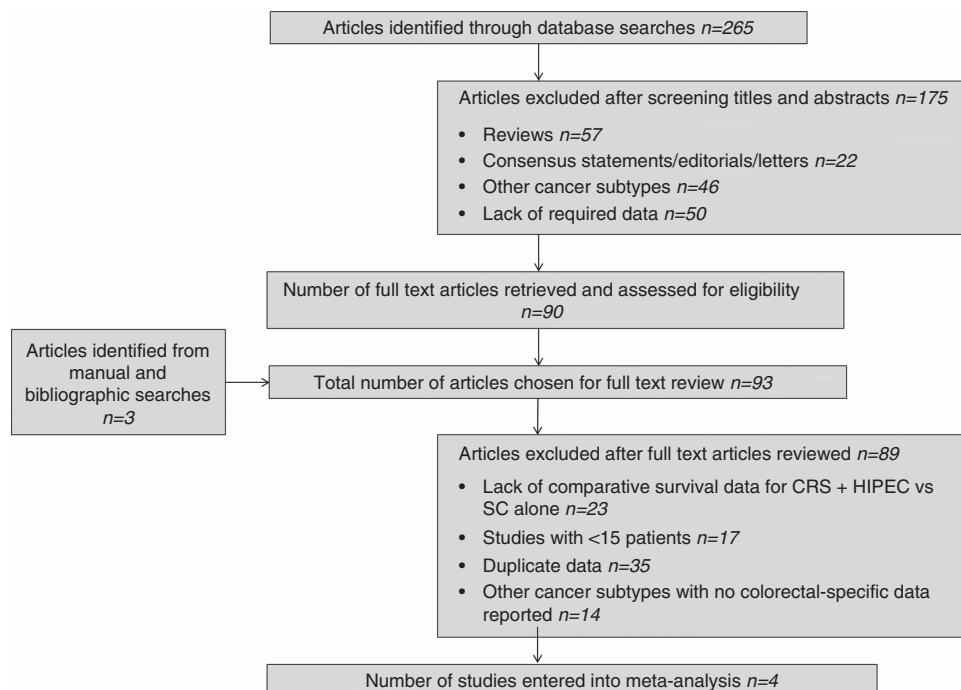

Figure 1. Modified PRISMA flow diagram summarising search strategy.

Table 1. Study design and treatment protocols

Author, year, location	Time frame	N	Study design (evidence level)	Indication	Extent of CPM	Treatment summary	Technique	Intraperitoneal chemotherapeutic regimen
Mahteme et al, 2004, Sweden	1991–1999	36 (18 vs 18)	Case-control (2-)	CPM <sup>a</sup>	—	Treatment arm: CRS + EPIC (n = 18) Control arm: SC (n = 18)	Closed abdomen technique	EPIC protocol: 5-FU 550 mg m <sup>-2</sup> in 500 ml normal saline administered intraperitoneally from POD 1. IV infusion of leucovorin (60 mg m <sup>-2</sup> ) commenced at 60 min after initiation of PIC. Regimen offered 1–8 courses as tolerated with 4–6 week interval between cycles. SC protocol: chemotherapeutic regimen not specified
Verwaal et al, 2008, Netherlands	1998–2001	105 (54 vs 51)	Randomised trial (1-)	CPM <sup>a</sup>	—	Treatment arm: CRS + HIPEC (n = 54) Control arm: systemic CT only (n = 51)	Open coliseum technique	HIPEC protocol: MMC 35 mg m <sup>-2</sup> at 40 °C for 90 min SC protocol: 5-FU (400 mg m <sup>-2</sup> ) + leucovorin (80 mg m <sup>-2</sup> ) weekly for 26 weeks
Elias et al, 2009, France	1998–2003	96 (48 vs 48)	Case-control (2-)	CPM <sup>b</sup>	Treatment arm: limited 27/48 Extended 21/48 Control arm: Limited 26/48 Extended 17/48 Not recorded 5/48	Treatment arm: CRS + HIPEC (n = 48) Control arm: SC (n = 48)	—	HIPEC protocol: Oxaliplatin 460 mg m <sup>-2</sup> in 2 l m <sup>-2</sup> at 43 °C for 30 min. Before HIPEC (during CRS) patients received IV 5-FU 400 mg m <sup>-2</sup> + leucovorin 20 mg m <sup>-2</sup> . SC protocol: Various regimens (5-FU-based 46/48; Capecitabine-based 1/48; Camptothecin 1/48)
Franko et al, 2010, USA	2001–2007	105 (67 vs 38)	Case-control (2-)	CPM <sup>a</sup>	—	Treatment arm: CRS + HIPEC (n = 67) Control arm: SC (n = 38)	Closed abdomen technique	HIPEC protocol: MMC 40 mg for 100 min SC protocol: Chemotherapeutic regimen(s) not clearly described

Abbreviations: CPM = colorectal cancer peritoneal metastasis; CRS = cytoreductive surgery; EPIC = early postoperative intraperitoneal chemotherapy; 5-FU = 5-fluorouracil; HIPEC = hyperthermic intraperitoneal chemotherapy; MMC = mytomycin C; POD = postoperative day; SC = systemic chemotherapy.  
<sup>a</sup>Patients with distant metastatic disease excluded.  
<sup>b</sup>Patients with extra-abdominal metastatic involvement excluded (LN-positive and liver-metastasised cases included).

Subanalysis of survival in patients treated with CRS + HIPEC found 5-year survival of 37 and 14% in cases of macroscopically radical and incomplete resection, respectively. Similarly, Verwaal et al (2008) reported overall 2- and 5-year survival of 40 and 19% in patients treated with CRS + HIPEC, compared with 22% and 10%, respectively, for patients receiving SC alone. The authors found survival to correlate significantly with the completeness of cytoreduction, with 5-year survival of 45%, 8%, and 0% in patients undergoing R1 (complete macroscopic tumour clearance), R2a (residual tumour nodules <2.5 mm in thickness), and R2b (residual tumour nodules >2.5 mm in thickness) resection, respectively. Elias et al (2009) reported 2- and 5-year survival and median survival of 81%, 51%, and 62.7 months, respectively, in 48 patients undergoing CRS + HIPEC compared with 48 matched patients receiving SC alone (65%, 13% and 23.9 months, respectively). No data were available for survival according to extent of CPM or completeness of resection. Franko et al (2010) reported the median survival of 34.7 months in patients treated with CRS + HIPEC, compared with 16.8 months with SC alone (P < 0.001). Forest plots summarising pooled analysis of survival

outcomes at 2 and 5 years with CRS + HIPEC vs SC alone are shown in Figures 2 and 3. Heterogeneity analysis revealed no significant between-study inconsistencies (2-year data: Q-value 3.14; df (Q) 3; P-value 0.377; I<sup>2</sup> 4.33; 5-year data: Q-value 2.66; df (Q); 3; P-value 0.488; I<sup>2</sup> 0.00), and consequently estimates for OR and corresponding CI were derived using the FEM. Our meta-analysis demonstrated a significant improvement in 2-year survival with CRS + HIPEC compared with SC alone (OR = 2.78; 95% CI 1.72–4.51; P = 0.001; funnel plot analysis shown in Figure 2). Similarly, meta-analysis of 5-year survival data from the four included studies revealed significantly enhanced survival at 5 years in patients treated with CRS + HIPEC compared with SC alone (OR = 4.07; 95% CI 2.17–7.64; P = 0.001; Figure 3).

**Morbidity, mortality, patient reported outcome measures, and health economics.** Two of the four studies provided morbidity and mortality data (Mahteme et al, 2004; Verwaal et al, 2008). Mahteme et al (2004) reported overall treatment-associated morbidity and mortality of 72% and 0%, respectively. Complications attributed to treatment with CRS + HIPEC in this study

included severe postoperative pain (4/18, 22%), persistent nausea and vomiting (2/18, 11%), transient neutropenia (1/18, 5.5%), prolonged ileus (1/18, 5.5%), and postoperative bowel obstruction (5/18, 27.5%). Verwaal *et al* (2008) reported a mortality rate of 7% (4/54) in the CRS and HIPEC group in the only randomised study in this field. In all cases this was secondary to the development of postoperative complications that included abdominal sepsis in two cases. Complications in this study were reported according to the WHO criteria, with an overall complication rate of 7% in 54 patients undergoing CRS + HIPEC. Specifically, the most common grade 3 toxicities reported were leukopenia (15%), heart failure (8%), haemorrhage (6%), and catheter-related infections (6%). The most common grade 4 toxicities were intestinal fistulae (15%), haemorrhage (8%), and renal failure (6%). Massive pulmonary embolus occurred in 4%. The remaining two studies included in this meta-analysis did not provide morbidity or mortality outcome data (Elias *et al*, 2009; Franko *et al*, 2010). Neither of the studies evaluated provided any published QOL/patient-reported outcome measures or health economic data for evaluation. Data from the one RCT in this field, however, were available for economic evaluation and were provided by the authors. Cost effectiveness calculations were conducted based on both medical and non-medical impact of the treatments and revealed that in an intention to treat analysis, the average CRS and HIPEC treatment was €17 286.00 (£14 334.81; \$24,005.07) more expensive than SC treatment. The additional costs of treatment were found to be consequent to the complications in the experimental arm and the resulting prolonged hospital stay (Verwaal, 2003).

DISCUSSION

Peritoneal metastasis from CRC presents significant challenges. Without treatment, all patients with CPM can expect to have an exceptionally impaired quality of life (QOL) and abbreviated survival. Conventional surgical resection in the context of CPM has not shown effectiveness and is associated with a median survival limited to 6 months or less (Mohamed *et al*, 2011). Similarly, orthodox systemic chemotherapeutic (SC) strategies for CPM have demonstrated limited efficacy, at least in part owing to the plasma-peritoneal barrier that significantly restricts intraperitoneal drug localisation.

For these reasons, alternative strategies have been sought, and aggressive multimodality treatment with CRS combined with HIPEC is one tactic proposed as a logical treatment strategy to improve long-term survival. In the past, this approach has been rarely applied due to concerns regarding treatment-associated morbidity and mortality and health-care-related costs and logistics (Khatri, 2010; Sugarbaker and Ryan, 2012). In more recent times, however, advances in radiological staging, surgical and anaesthetic practice, improved experience in chemotherapeutic methods, better management of surgical complications and chemotherapy-related toxicity, and an increasing centralisation of complex cancer services have helped expand the treatment options for patients with CPM, and improved the results of CRS and HIPEC in this setting.

Despite a recent consensus statement published on the role of CRS and HIPEC (Esquivel *et al*, 2007), there remains disagreement regarding the precise role of this multimodality approach in the treatment algorithm for CPM. In view of the ongoing debate, the aim of the present study was to perform meta-analytical assessment of medium- and long-term survival outcomes in patients with CPM treated with CRS and HIPEC compared with SC alone, which has hitherto represented the mainstay of treatment. Data from four studies, comprising three case-control studies and one RCT, with a cumulative total of 342 patients, were subjected to pooled analysis. We specifically excluded any data on patients with mucinous appendiceal peritoneal metastases receiving CRS and HIPEC because of the significant variation in the natural history and prognosis of this subgroup of patients (Sugarbaker and Jablonski, 1995).

Our pooled analysis demonstrates, for the first time, a significant improvement in survival at 2 and 5 years following CRS + HIPEC compared with standard treatment. This finding is likely explained by two fundamental points; first, the CRS component by definition leads to a reduction in tumour volume, which has long been recognised as an important determinant of tumour response to chemotherapy (Cotte *et al*, 2009). Second, the instillation of hyperthermic chemotherapeutic agents into the

Table 2. Two- and five-year survival outcomes following CRS + HIPEC vs SC alone

Figure 3. Summary of meta-analysis results for 5-year survival following CRS + HIPEC vs SC alone. The diamond represents the overall treatment effect, and squares are treatment effects for individual studies with 95% CI indicated by horizontal bars.

peritoneal cavity after CRS aims to destroy any remaining tumour cells and mitigates problems associated with poor peritoneal penetration achieved by conventional chemotherapy. Thus, these strategies in combination represent a highly logical and synergistic approach for the management of CPM.

The incremental contributions of either CRS or HIPEC to improved survival independently within this multimodality approach remain unclear from the currently available literature. A recent study by Huang *et al* (2013) compared outcomes in 29 patients undergoing CRS alone, with 33 patients treated with CRS and HIPEC in combination. All patients received adjuvant SC with FOLFOX or FOLFIRI regimens. The authors found significantly improved 1-, 2-, and 3-year survival in patients treated with CRS + HIPEC compared with CRS alone. A multi-centre French randomised trial (PRODIGE 7) comparing CRS and HIPEC against CRS only for CPM with a PCI stage of less than 24 has recently completed accrual, and preliminary results are awaited. To date, no trial has evaluated outcomes with HIPEC in isolation vs CRS + HIPEC or SC only; however, such a study may not be forthcoming, given what is currently known regarding the association between tumour bulk reduction and chemotherapeutic effectiveness. With regards to SC alone for treatment of CPM, an unavoidable problem, even with newer chemotherapeutic agents and targeted therapies, lies in the fact that patients with peritoneal malignancy frequently develop bowel obstruction, which will, in many cases, prohibit completion of therapy. It is unclear from the data evaluated in the present study what proportion of patients receiving SC in isolation had their treatment courses truncated because of such complications.

Several misapprehensions must be set aside in order for CRS + HIPEC to be accepted as 'gold standard' therapy for selected patients with CPM. First, it has been suggested that the evidence base to support the role of CRS + HIPEC is limited. However, we would contend that unlike the management of hepatic and pulmonary metastases from CRC, which have never been subjected to randomised evaluation and currently represent the standard of care, there are level 1 data available showing the advantages conferred by CRS and HIPEC compared with SC alone. Moreover, this finding is further endorsed by all the case-control studies evaluated in the present meta-analysis.

Second, it has been suggested that the morbidity and mortality associated with CRS + HIPEC is unacceptably high. However, without this aggressive approach, the median survival from CPM seldom exceeds 6 months, and this abbreviated period is frequently beset by symptoms of severe abdominal pain and bowel obstruction, as well as systemic toxic consequences associated with SC. Unquestionably, the combination of extensive multi-visceral resection, prolonged operation time, and intraperitoneal chemotherapy will confer a considerable potential for surgical complications, toxicity, and impairment of QOL. The most feared

treatment-associated complications identified include fistula formation, anastomotic dehiscence, postoperative bleeding, nephrotoxicity, and haematological complications. However, improvements in anaesthesia, operative technique, critical care, and diagnostic and interventional radiology are facilitating better results through early recognition and active treatment of complications, with several recent large-scale studies now reporting acceptable morbidity and mortality following CRS + HIPEC (Canda *et al*, 2013; Bakrin *et al*, 2013). In addition, more effective means of predicting likely treatment-associated morbidity and mortality are emerging, which will further improve patient selection (Ihemelandu *et al*, 2013). For example, a recent study by Ihemelandu *et al* (2013) found that preoperative use of the Functional Assessment of Cancer Therapy questionnaire combined with Eastern Cooperative Oncology Group performance allowed enhanced prediction of treatment-associated morbidity and mortality. Furthermore, a recent study by Passot *et al* (2013) evaluated QOL following CRS + HIPEC for peritoneal carcinomatosis and found, as expected, a reduction in QOL in the first 6 months after aggressive multimodality therapy. However, the authors also noted that QOL returned to baseline at 12 months post CRS + HIPEC, by which time few, if any, patients not receiving radical treatment would be expected to have survived.

With respect to health-care costs associated with CRS + HIPEC, only one study included in this meta-analysis provided expense-related data (Verwaal, 2003). Results of this intention to treat analysis showed that CRS and HIPEC treatment was €17 286.00 more costly than SC, with the additional expenses principally because of development of complications necessitating prolonged hospital stay. A limited number of other studies have also performed cost-effectiveness analysis, but in a non-comparative setting. For example, Chua *et al* (2010) performed cost-effectiveness analysis on 136 consecutive patients who underwent a total of 159 CRS + HIPEC procedures over a 6-year period at a single tertiary referral centre. They reported average costs per patient and per life year of AUD \$66 148 and AUD \$29 757, respectively, for patients treated with CRS + HIPEC for CPM. The authors concluded that this treatment approach is associated with increased medical care costs, but that these costs are offset by the treatment-associated gains in observed life years. In the medium term, the additional costs associated with CRS and HIPEC will likely further diminish, because of improved patient selection for radical treatment, and with increasingly better management of treatment-related complications, in line with most complex surgical interventions.

There are a number of both limitations and strengths to the present analysis. All but one of the studies evaluated in this meta-analysis were non-randomised comparative studies with small to modest sample sizes, and not the highest quality evidence. Nevertheless, it remains unclear whether meta-analyses of non-

randomised studies systematically overestimate effect sizes compared with meta-analyses of randomised trials (MacLehose *et al*, 2000), and in light of the scarcity of high-quality evidence in this field, data from the meta-analysis of non-randomised studies can be informative. A further criticism is that the studies examined showed significant variability with respect to the extent of peritoneal disease in affected patients, its manner of assessment, treatment protocols, and the type of chemotherapy applied. Clearly therefore our findings must be interpreted with a degree of caution, nevertheless through combining data, the effect of bias within individual studies may also be mitigated partly. Importantly, our findings do not advocate resection of all cases of CPM but highlight the importance of selection criteria used and the advantages of judicious patient assessment. Better methods of patient selection are clearly necessary, however, and the role of physiological testing preoperatively may well merit further study to more effectively gauge functional capacity and risk of adverse events. In addition, several studies have shown a clear association between extent of disease and oncological outcome (Verwaal *et al*, 2004), highlighting the urgent need for more precise radiological methods for preoperative assessment of disease location and burden. Current CT- or FDG-PET-based methods of cancer evaluation are dependent on the amount of tumour per square centimetre and are thought to generally underestimate the extent of peritoneal surface malignancy, which will often not fulfill the RESIST criteria of 1 cm in diameter for measurable disease (Verwaal *et al*, 2008). In addition, an important challenge on the horizon will be to identify methods to avoid over-treatment in patients with chemotherapy-insensitive tumours, and to limit side effects in those with chemosensitive disease. The exact type of chemotherapy and its method of administration also remain unclear at the present time, as is the precise contribution of CRS or HIPEC to the favourable outcomes observed. A further key question will be whether different/more radical/dose-escalated HIPEC/intraperitoneal chemotherapy regimens can counter unfavourable peritoneal disease extent scores. Robust molecular biomarkers of oncological outcome and disease response are clearly required and are presently lacking. Exciting developments in the molecular sciences and the multi-platform high-throughput methods increasingly applied to diverse tumour types are slowly revolutionising established treatment approaches, and raise hopes of a more personalised strategy in the future treatment of CPM. The currently active molecularly stratified COMBATAC multicentre trial in CPM may help further advance this field and address some of the questions in the near future (Glockzin *et al*, 2013).

In summary, the present meta-analysis indicates that, although the evidence base for adoption of CRS and HIPEC is generally composed of low evidence level studies from uncontrolled retrospective series, there are comparative and prospective studies available, and arguably a greater body of data exists for this treatment option than has been available to support the use of metastatectomy for liver and lung metastases of CRC origin. Moreover, the available studies consistently demonstrate survival and symptom control rates far greater than any available alternative, justifying an aggressive multimodality approach. Consequently, analogous to the acceptance of surgery for liver and lung metastatic CRC, surgery for CPM should have an established place in selected patients and offers the only realistic chance of long-term survival. Indeed, a case could be made that the biological arguments for treatment of peritoneal only metastases are more persuasive than those for surgery of CRC that has metastasised to distant organs. Metastasis to distant organs is a consequence of a complicated multistep process, wherein cells acquire the ability to invade beyond normal cellular boundaries, intravasate into blood and lymphatics, journey to distant organs, extravasate and proliferate in a different microenvironment, concomitantly eluding antitumour host immunity. By contrast,

CPM arising from the shedding and exfoliation of CRC cells able to survive and grow on the peritoneal surface, but which lack the capacity to disseminate, is more likely to represent a better prognostic tumour type, by lacking the molecular capacity to spread to distant organs. Greater recognition of the concept of curative CPM should ultimately lead to earlier referral to specialist units, resulting in improved completeness of resection and better survival outcomes.

## CONCLUSIONS

The present meta-analysis demonstrates a clear and significant improvement in survival at 2 and 5 years following CRS + HIPEC compared with SC alone. The studies included are small in number and of variable methodological quality, with only one RCT. Nevertheless, our findings support a growing body of data that suggests that CRS + HIPEC can result in survival rates greater than any alternative. Management decisions for CPM are complex, and treatment requires multidisciplinary, multimodality approaches. In view of these complexities, optimal assessment and management is best undertaken by specialist units able to provide the breadth of expertise and options required. Importantly, the present study has also identified a number of unanswered questions to inform the design of future studies. To address these, high-number, multi-institutional studies with limited heterogeneity in assessment and treatment protocols will better enable clarification of some of the remaining controversies in the treatment of CPM, and serve as a platform for incremental advances towards the optimal treatment of metastatic CRC.

## ACKNOWLEDGEMENTS

AHM is supported by grant funding from Cancer Research UK (C28503/A10013). This study was funded by the Cancer Research UK and Royal College of Surgeons of England.

## CONFLICT OF INTEREST

The authors declare no conflict of interest.

## DISCLAIMER

The funding sources had no role in the collection, analyses, interpretation of data, writing of the report, or decision to publish.
