A rich collection of empirical findings accumulated over the past three decades attests to the diversity of traits that constitute the autism phenotypes. It is unclear whether subsets of these traits share any underlying causality. This lack of a cohesive conceptualization of the disorder has complicated the search for broadly effective therapies, diagnostic markers, and neural/genetic correlates. In this paper, we describe how theoretical considerations and a review of empirical data lead to the hypothesis that some salient aspects of the autism phenotype may be manifestations of an underlying impairment in predictive abilities. With compromised prediction skills, an individual with autism inhabits a seemingly “magical” world wherein events occur unexpectedly and without cause. Immersion in such a capricious environment can prove overwhelming and compromise one’s ability to effectively interact with it. If validated, this hypothesis has the potential of providing unifying insights into multiple aspects of autism, with attendant benefits for improving diagnosis and therapy.

1. The Hypothesis of Predictive Impairment in Autism

An essential component of a magical phenomenon is the lack of a discernible cause: An event that we are unable to predict happens “as if by magic.” Given how well-honed our predictive abilities are, magicians have to resort to clever contrivances to achieve their mystifying effects. However, if our predictive abilities were somehow to be compromised, then even mundane occurrences in the environment might appear magical. Although a brief magical performance is enjoyable, unrelenting immersion in it can be overwhelming. A magical world suggests lack of control and impairs one’s ability to take preparatory actions. It can result in outcomes such as those that constitute the autism phenotypes. This idea is the crux of the hypothesis we develop here.

Theoretical motivation for the hypothesis that autism may be associated with a decreased ability to discern predictive relationships between environmental entities derives from the information processing demands inherent in the domains that are typically affected in autism. The primary diagnostic criteria for autism (1, 2)—social communication difficulties and restricted and repetitive behaviors—are superficially quite distinct from each other. However, they are quite similar from an information theoretic perspective: The underlying domains all constitute temporally unfolding Markov systems, with progressions from one state to another governed by probabilistic links (Fig. 1A). A large body of past work has shown how each of these domains maps onto such a formalism (3–13), albeit at different time-scales.

To perform well in these domains, one necessarily needs to estimate the underlying Markov system, i.e., the matrix of interstate transition probabilities. The fundamental prerequisite for such estimation is the extraction of state-to-state probabilities from observed event streams. As depicted in Fig. 1B, from an observed temporal sequence, the brain has to estimate the

conditional probability $P(B|A, \Delta t)$, the likelihood of transitioning to state “B” given the occurrence of “A” and elapsed temporal duration, Δt . The hypothesis of predictive impairment in autism (PIA) posits that autism may be associated with inaccuracies in estimating the $P(B|A, \Delta t)$ conditional probability.

Fig. 2A depicts the PIA hypothesis schematically. Two key parameters characterize any interevent relationship: strength [$P(B|A)$] and temporal separation (Δt). In this 2D space, relationships toward the lower right may be undetectable, given that they have weak strength (B does not consistently follow A) and require integration over a large time interval (B occurs long after A has transpired). By contrast, relationships toward the upper left would be easier to detect. The association sensitivity function (ASF) defines the interface between detectable and undetectable relationships. A reduction in one’s predictive ability would, in this space, manifest as a shift of the ASF toward the upper left. As a consequence of this shift, several relationships that are evident to a neurotypical individual would become undetectable to a person with autism.

Autism likely owes its genesis to a multiplicity of causes. We present the PIA hypothesis not as the sole causal factor underlying the condition, but rather as one that may provide an explanatory account of a few different aspects of the autism phenotype. Our hope is that as a theory, PIA may be able to help define some concrete avenues for further research into the causes of, and interventions for, autism. In the following sections, we consider the potential of this hypothesis to account for several important aspects of the autism phenotype (Section 2),

Significance

Autism is characterized by diverse behavioral traits. Guided by theoretical considerations and empirical data, this paper develops the hypothesis that many of autism’s salient traits may be manifestations of an underlying impairment in predictive abilities. This impairment renders an otherwise orderly world to be experienced as a capriciously “magical” one. The hypothesis elucidates the information-processing roots of autism and, thereby, can aid the identification of neural structures likely to be differentially affected. Behavioral and neural measures of prediction might serve as early assays of predictive abilities in infants, and serve as useful tools in intervention design and in monitoring their effectiveness. The hypothesis also points to avenues for further research to determine molecular and circuit-level causal underpinnings of predictive impairments.

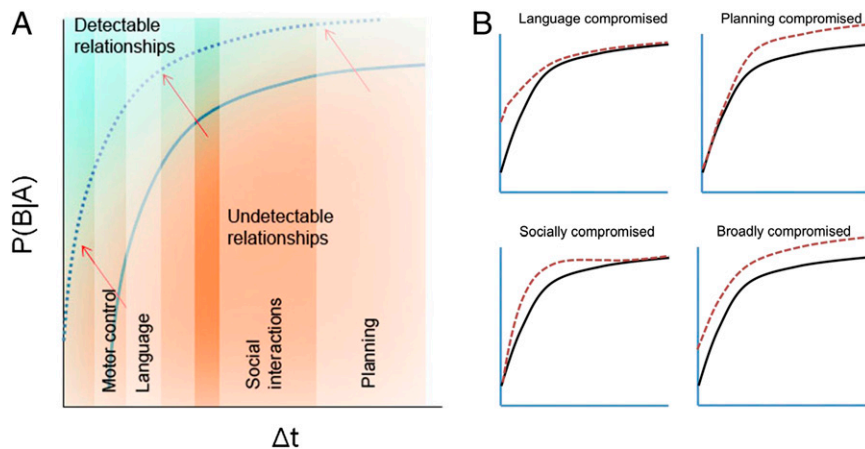

Fig. 2. (A) A schematic depiction of the PIA hypothesis. Relationships between two events can be characterized by their strength [$P(B|A)$] and temporal separation (Δt). In this space, the interface between undetectable and detectable relationships marks the ASF, denoted by the solid curve here. The PIA hypothesis posits that autism is accompanied by a shift of the ASF toward the upper left (red arrows) corresponding to a reduction in one's sensitivity to relationships that are weak and/or have large temporal spans. This shift renders some interevent relationships, which are evident to neurotypical individuals, invisible to those with autism. The vertical bands indicate that different tasks rely on the detection of interevent relationships over varying time-scales. For instance, whereas motor-control and language learning operate in the millisecond regime, social interactions and planning involve longer time intervals. (B) Behavioral manifestations of PIA may differ depending on which temporal regimes experience the greatest ASF shifts. As depicted in the four small graphs, different autism subtypes may arise in part from ASF shifts of different kinds.

impairment causes environmental stimuli to appear more chaotic, leading to reduced habituation and hence greater stress.

3. Difficulties in Interacting with Dynamic Objects. The dynamic world presents challenges to those with autism. The Autism Wandering and Elopement Initiative collaboration states that two in three “elopers” (autistic children who attempt to run away) have a close call with a traffic injury (39). According to the Center for Advanced Infrastructure and Transportation at Rutgers University, the vast majority (more than 75%) of people on the autism spectrum cannot drive (40). In first-person accounts, individuals with autism describe the difficulties they had as children engaging in dynamic games on the playground (41). These reports are puzzling given that moving objects are not inherently aversive to those with autism. Indeed, many children on the spectrum are especially drawn to moving objects, enjoy video games (42), obsessively set objects in motion, and even engage in visual stimming that generates movement. What then underlies autistic individuals' difficulties with dynamic objects?

It is instructive to examine the specific nature of these difficulties. Several studies have shown that basic motion detection and direction perception thresholds are largely unimpaired in autism (43–45). However, to interact with a dynamic object, there is a crucial step beyond detection: anticipating where the moving object is likely to be so as to plan one's motor movements appropriately to intercept/avoid the object. Even the seemingly simple task of keeping track of a moving object requires such anticipation; it is a manifestation of online Markov model estimation, as a visual temporal sequence unfolds. Computational systems for dynamic object tracking rely on predictive techniques such as Kalman filtering (46). These systems demonstrate that a key consequence of impaired prediction is errors in online position estimation. Transposed to the real world, this impairment would render seemingly straightforward tasks like avoiding a car or even catching a ball difficult for a person with autism.

Consider the following first person account:

Throwing a ball was not a problem. However, I couldn't catch a ball until I was Age 13! I was criticized by my father about my ability, or lack of, to work with my hands.

(Jon Evans on www.DisabilityScoop.com)

Given the prediction-reliant nature of tasks requiring interactions with dynamic objects, the PIA hypothesis provides a plausible account of the difficulties that individuals with autism encounter in such settings.

4. Difficulties with Theory of Mind. Theory of mind requires the ability to ascribe invisible causes to observations about a person by connecting past history with current behavior. Deducing why a person acted a certain way, or anticipating how a person is likely to act, requires the estimation of a conditional probability: Given a certain observation about a person and the circumstances, what are the likely precursors leading up to them, and in a similar vein, what are the next stages in their evolution? In this sense, Theory of mind is inherently a prediction task—given an observation, one has to postdict or predict its antecedent or subsequent states, i.e., estimate $P(\text{past history} | \text{current behavior})$ or $P(\text{future actions} | \text{current observations})$. Given the often-weak relationships among history, present observations, and future behavior for humans in social settings, these states involve the estimation of challenging probabilities and, hence, are especially vulnerable to impairments in predictive ability. Impairments in Theory of mind are a prominent correlate of autism (47).

Impairment in prediction would render an observer unable to situate current observations about a person in the context of their antecedents or likely future states. The observer, in effect, will be constrained to interpret observations “in the moment.” Such interpretations would manifest themselves as being literal, in that they describe what is happening from moment to moment, but are not influenced by past history and do not presage future events. The minimalistic movies of Heider and Simmel provide an interesting case in point (48). Having access to a probabilistic conditional relationship between observed movement patterns and potential histories, neurotypical individuals are able to ascribe causes to the former. The fact that these causes happen to be social in nature is likely happenstance; the social account is simply a better predictor of the observations than other historical accounts. An autistic individual, not having access to such predictive relationships, is constrained to interpret behaviors without any motivating history, social or otherwise (49).

In this way, the PIA hypothesis provides a simple account of the difficulties autistic individuals experience with theory of mind

and other abstractions, which require the use of learned interevent relationships to read more into an observation than the basic sensory signal offers.

5. Islands of Proficiency. Individuals with autism have been reported to show preserved, or even enhanced, abilities relative to neurotypical controls in several domains (50). These islands of proficiency include mathematics (51), static form coherence (52), visual search (53, 54), block design tasks (55), calendar calculations (56, 57), musical performance (50, 58), and drawing abilities (59, 60). These seemingly distinct domains share an important characteristic. Most of them, especially mathematics calendar calculations and music, are strongly rule-based, and, thus, minimize uncertainty of outcomes. Furthermore, with the exception of music, they are static, thereby obviating the need for prediction over time. If the prediction systems of the brain are differentially affected in autism, then one can expect that the skills left largely untouched would be the ones that are deterministic and where good performance does not depend on estimates of temporally unfolding conditional probabilities.

An examination of studies of preserved or enhanced proficiency in music (61, 62) reveals that the observed high performance is typically in replication. The reports further note that such factors as perfect pitch, prodigious memory, and extensive rehearsal, while contributing to the extraordinary skill set, are not sufficient to explain it (50, 58, 60). Detailed studies of musical savants with autism reveal that the basis for exceptional recall and performance, including improvisation, is familiarity with the structure of music and, thus, depends on adherence to rules (63).

As the foregoing discussion suggests, the PIA hypothesis provides a parsimonious account of some notable aspects of the autism phenotype. We next consider some empirically testable predictions this hypothesis makes about other traits that “should” be observed in individuals with autism.

3. Predictions Arising from the PIA Hypothesis

1. Hyperplasticity. An important outcome of reduction in predictive abilities is a heightening of the perceived novelty of environmental stimuli. This enhanced novelty has a potentially interesting consequence on learning. It is known that activity in the brainstem and basal ganglia is modulated by novelty (64). Furthermore, significant evidence suggests that these structures play an important role in modulating learning (65, 66). Given the elevation of novelty due to impaired predictive skills, one would expect hyperactivation of the brainstem and basal ganglia in individuals with autism. Hyperarousal of these structures would, in turn, be expected to lead to hypermalleability of learning; current exposure would have disproportionate weight and supersede earlier experience, constituting a kind of “hyperplasticity.” Notably, such hyperplasticity would, in turn, further impair instance aggregation and, thus, an accurate estimation of probability values. Interestingly, precisely such hyperplasticity has been reported in mouse models of autism (67).

2. Changes in Striatum, Basal Ganglia, and Cerebellum. In neurotypical individuals, the key brain loci that have been implicated in prediction are basal ganglia (68, 69), striatum (70, 71), anterior cingulate (72), and cerebellum (73, 74). If predictive abilities are affected in autism, then we would expect these regions of the brain to be especially implicated. Indeed, the emerging picture from recent neuro-imaging, postmortem, and animal-model studies is that atypicalities in these regions are associated with autism (75–80).

3. Reduced Appreciation of Humor. A key component of humor is violation of expectation (81, 82). This implicitly requires the listener to have a prediction of how a given sequence is likely to

unfold. A benign deviation from that prediction often constitutes a humorous outcome (82). In the absence of a strong prediction, a violation is harder to define and detect. Hence, opportunities for perceiving humor in narratives or observations are diminished. With this logic, the PIA hypothesis predicts that the sense of humor of individuals on the autism spectrum would be diminished or at least altered relative to that of neurotypicals.

Although systematic research on how autism affects the sense of humor is still in its infancy, some evidence supports this prediction. In describing his patients, Hans Asperger had noted that “an essential characteristic of these children is their humorlessness. They do not understand jokes. . .” (83). More recent studies (84, 85) have also documented these observations. It is particularly interesting to note Emerich et al.’s (86) finding that adolescents with autism had special difficulty “handling surprise and coherence within humorous narratives.”

4. Reduced Motor Anticipation. Starting from a very early age, much of human motor behavior is anticipatory in nature. Whether it is adopting appropriate foot placement and body-posture while walking on uneven ground, or mouth shaping during speech articulation, there is extensive evidence for motor anticipation (87–89). The PIA hypothesis predicts that motor anticipation would be reduced in individuals with autism. The evidence so far is generally consistent with this prediction (90, 91). Even in his initial case reports, Kanner (92) noted poor anticipation on the part of autistic children to being picked-up by their parents. More recently, in a retrospective analysis Brisson et al. (93) have reported anticipatory failure during feeding situations in infants between 4 and 6 mo old who were later diagnosed as having autism. Fournier et al. (94), among others (95, 96), have found poor postural control in children with autism. Given that anticipatory processes have been implicated even in the maintenance of muscle tone (97), the PIA hypothesis might also help account for some aspects of hypotonia observed in children with autism.

4. Conclusion

Autism can have many etiologies, and yet, there is some commonality across manifestations, hence a shared clinical diagnosis. Based on theoretical considerations and a review of past literature, we believe that predictive impairment may constitute an endophenotype shared across individuals. This hypothesis may be a way to conceptualize a disorder that otherwise seems too heterogeneous and polymorphic. However, the notion of core impairments, shared by most cases of autism, seems to be at odds with the heterogeneity of the phenotype. How can the same basic impairment manifest itself so differently across different individuals? There are two points to note in responding to this concern.

First, despite the heterogeneity across cases of autism, there is also preserved commonality (98–100). Experienced clinicians are able to detect these core traits to reach their diagnostic assessments quickly. Thus, it would be misleading to think that the observed heterogeneity entirely overwhelms similarities. The PIA hypothesis is an attempt to characterize the shared aspects of autism. It is an idea similar in spirit to the recent finding of shared gene networks across many autism subtypes (101).

Second, the PIA hypothesis does not require that the predictive impairment be identical across all individuals; under the umbrella PIA hypothesis, there may well be parametric variations, as depicted in Fig. 2*B*. For instance, two children, both of whom have a predictive impairment, may differ in terms of the strength of predictive relationships they are able to detect, and the temporal regimes in which the predictive impairments are most pronounced. Impairments in the millisecond range might be more disruptive to language learning than those in the multisecond range, which may differentially affect social interactions

instead. Such parametric differences may help account for the phenotypic variability observed across individuals on the autism spectrum and also potentially provide the basis for a principled taxonomy of different autism subtypes.

Another question that we have to consider in evaluating PIA is the need for such a hypothesis; Are there alternative explanations for aspects of the autism phenotype that we have tried to account for using PIA?

Explanatory accounts have indeed been offered for each of the autistic traits we have described in *Sections 2 and 3*. For instance, difficulties in Theory of Mind have been suggested as arising from abnormalities of the cortical substrates for social cognition (102) or in the mirror neuron system (refs. 103 and 104 but see 105). Motor difficulties are believed to arise from abnormalities in the cerebellum (106). The list goes on. The general point is that explanations exist, but are typically tied to specific traits. Although it is certainly possible that the different autistic traits have different etiologies, what is appealing about the PIA hypothesis is its parsimony—an account that is able to provide a unifying explanation for not just a single trait, but for several of them. Indeed, some recent data show that superficially very different aspects of the autism phenotype may, in fact, be linked. Cathy Lord and her coworkers (107) have found that the ability to throw or catch a ball is correlated with social skills success in children with autism. Although not conclusive evidence, this further lends support to the possibility of shared causality for seemingly different behavioral traits.

The hypothesis of a predictive impairment may not only help us better understand the information processing roots of the

autism disorder, but also serve as a precursor to identifying the brain regions that are involved in these probabilistic processes and, perhaps, are differentially affected in autism. This program of research can build on the exciting body of recent work that has been investigating the prediction and reward machinery in the neurotypical brain, both in humans and other animals (108). Moving further down the causal chain, the methods of behavioral genetics can help examine genetic underpinnings of predictive abilities and, thereby, suggest candidate risk genes for autism. These studies could prove to be useful complements to those already underway by using linkage and copy number variation analyses (e.g., ref. 109). This approach would enable linkages to be made between the manifest traits of autism and the underlying genetic architecture. Reliable behavioral tests and neural markers of prediction may serve as early assays of these abilities in infants at risk and also be useful as tools to monitor the effectiveness of therapeutic interventions (as demonstrated in ref. 110).

Perhaps one beneficial outcome of this work will be to balance the sense of being overwhelmed by a relentlessly magical world with the feeling of tedium in the frequently mundane world of neurotypicals. By occasionally getting a glimpse of both worlds, we may be able to enrich all lives.

ACKNOWLEDGMENTS. We thank Drs. Helen Tager-Flusberg, Charles Nelson, and Geraldine Dawson for discussions and several parents of children with autism for comments.
