ABSTRACT Recently, we demonstrated the utility of optical fluorometry to detect a change in the redox status of mitochondrial autofluorescent coenzymes nicotinamide adenine dinucleotide (NADH) and oxidized form of flavin adenine dinucleotide (FADH₂) (FAD), as a measure of mitochondrial function in isolated perfused rat lungs (IPL). The objective of this paper was to utilize optical fluorometry to evaluate the effect of rat exposure to hyperoxia (>95% O₂ for 48 h) on lung tissue mitochondrial redox status of NADH and FAD in a nondestructive manner in IPL. Surface NADH and FAD signals were measured before and after lung perfusion with perfusate containing rotenone (ROT, complex I inhibitor), potassium cyanide (KCN, complex IV inhibitor), and/or pentachlorophenol (PCP, uncoupler). ROT- or KCN-induced increase in NADH signal is considered a measure of complex I activity, and KCN-induced decrease in FAD signal is considered a measure of complex II activity. The results show that hyperoxia decreased complex I and II activities by 63% and 55%, respectively, when compared to lungs of rats exposed to room air (normoxic rats). Mitochondrial complex I and II activities in lung homogenates were also lower (77% and 63%, respectively) for hyperoxic than for normoxic lungs. These results suggest that the mitochondrial matrix is more reduced in hyperoxic lungs than in normoxic lungs, and demonstrate the ability of optical fluorometry to detect a change in mitochondrial redox state of hyperoxic lungs prior to histological changes characteristic of hyperoxia.

INDEX TERMS NADH dehydrogenase (complex I), succinate dehydrogenase (complex II), flavin adenine dinucleotide (FADH₂), Nicotinamide Adenine Dinucleotide (NADH), lung surface fluorometry, mitochondrial redox.

I. INTRODUCTION

HIGH oxygen (O₂) therapy (hyperoxia) is a necessary treatment of low blood O₂ in adult and pediatric patients with acute lung injury (ALI) [1]–[3]. This treatment is effective in restoring blood pO₂ to a level which sustains vital organ metabolic requirements. However, prolonged exposure to high O₂ concentrations (>50%) causes lung injury [3]–[7]. Further complicating this situation is the fact that the time frame over which hyperoxic lung injury develops is difficult to predict due to the wide variation between patient

tolerance/susceptibility [8]. Thus, a minimally invasive method to detect pulmonary injury in an individual patient exposed to high fractions of O₂ in real time is highly desirable.

Rat exposure to >95% O₂ is a well-documented model of hyperoxic lung injury and human ALI [5], [8]–[10]. Previous studies have suggested that mitochondrial dysfunction is a cardinal feature of hyperoxic lung injury [11]–[16]. Although much work has been done in cell cultures and tissue homogenates, studies probing key tissue mitochondrial

with bandwidths of 40 nm and 50 nm, respectively. Finally, the filters used to detect the emitted fluorescence are centered at 460 and 520 nm, respectively, each with a bandwidth of 40 nm.

C. ANIMALS

For normoxic (control) lung studies, adult male Sprague-Dawley rats (Charles River; 300-350 g) were exposed to room air. For the hyperoxic lung studies, age matched rats were housed in a Plexiglass chamber maintained at >95% O₂ for 48 hours (hyperoxic) [21]. The total gas flow was 3.5 liters/min and the chamber CO₂ was maintained at <0.5%. The temperature within the chamber was 20-22°C. Every other day, the rats were weighed, and their cage, food, water, and CO₂ absorbent were changed. All rats were kept on a 12:12-h light-dark cycle. A total of 17 normoxic and 16 hyperoxic rats were studied. All animal experiments were performed under the approval of Institutional Animal Care and Use Committees of the Zablocki Veterans Affairs Medical Center and Marquette University (Milwaukee, WI) and in compliance with the National Research Council's Guide for the Care and Use of Laboratory Animals. For the hyperoxic rats, the optical imaging and other studies described below were conducted immediately following the exposure period.

D. ISOLATED PERFUSED RAT LUNG PREPARATION

The isolated perfused lung preparation allows for manipulation of lung tissue mitochondrial redox state without disrupting the multi-cellular environment of the lung through the addition of metabolic inhibitor(s) to the recirculating perfusate and/or alteration of the composition of the ventilation gas [18].

As previously described, rats were anesthetized with pentobarbital sodium (40 mg/kg body wt. i.p.), the chest opened and heparin (0.7 IU/g body wt.) injected into the right ventricle [18]. The pulmonary artery and the trachea were cannulated, and the pulmonary venous outflow was accessed via a cannula in the left atrium. The heart-lung was removed from the chest and attached to a ventilation and perfusion system. The control perfusate contained (in mM) 4.7 KCl, 2.51 CaCl₂, 1.19 MgSO₄, 2.5 KH₂PO₄, 118 NaCl, 25 NaHCO₃, 5.5 glucose, and 3% fatty-acid free bovine serum albumin (BSA) [22]. The perfusion system was primed (Masterflex roller pump) with the control perfusate maintained at 37°C and equilibrated with 15% O₂, 6% CO₂, balance N₂ resulting in perfusate pO₂, pCO₂ and pH of ~105 Torr, 40 Torr, and 7.4, respectively. Initially, control perfusate was pumped through the lung until it was evenly blanched and venous effluent was clear of blood. The lung was ventilated (40 breaths/min) with end-inspiratory and end-expiratory pressures of ~6 and 3 mmHg, respectively, with the above gas mixture. The pulmonary arterial pressure was referenced to atmospheric pressure at the level of the left atrium and monitored continuously during the course of the experiments. The venous effluent pressure was atmospheric pressure.

E. EXPERIMENTAL PROTOCOLS

Lung surface fluorescence measurements: The fluorometer was used in a dark room to minimize stray-light effects [18]. Surface fluorescence was then measured by placing the fiber optic probe against the pleural surface of the right lobe. For a given lung, NADH and FAD surface fluorescence signals were first acquired under resting conditions (lung perfused with control perfusate and ventilated with 6% CO₂ balance O₂ ventilation gas), and then following the addition of one or more of the following agents (rotenone, potassium cyanide, and pentachlorophenol) to the recirculation perfusate. Rotenone (20 μM) was used to inhibit mitochondrial complex I activity (Fig. 2), which would be expected to increase NADH signal by reducing the chain upstream from complex I. As a mitochondrial complex IV inhibitor (Fig. 2), potassium cyanide (KCN, 2 mM) would be expected to reduce the chain upstream from complex IV and hence increase NADH signal, and decrease FAD signal from succinate dehydrogenase (complex II) Uncoupled mitochondrial condition was achieved by the addition of pentachlorophenol (PCP, mitochondrial uncoupler; 3 mM) to the recirculating perfusate. As a protonophore, PCP should oxidize the chain and hence decrease NADH signal and increase FAD signal (Fig. 2). For some of the lungs, KCN was added after the initial addition of rotenone or PCP to the recirculating perfusate. The above concentrations of rotenone, KCN, and PCP were chosen to achieve maximal inhibition or uncoupling and hence maximal changes in NADH and/or FAD signal based upon published reports [11], [18].

At the end of the above imaging protocol, a subset of normoxic and hyperoxic lungs were fixed inflated with paraformaldehyde, paraffin embedded, sectioned in 5 micron thick whole mounts, then stained with hematoxylin and eosin (H&E) staining.

F. FLUORESCENT SIGNAL PROCESSING

The signal measured by the fluorometer contains a time shared sequence of NADH and FAD pulses collected from the surface of the lung. Superimposed over the signal for NADH or FAD is lung ventilation noise. To remove this noise, the trend of the data was first calculated by extracting the maximum value of each pulse. This trend was then smoothed out using a fourth order median filter followed by a fourth order moving average filter. The resulting NADH and FAD signals were then normalized by dividing each by its baseline value (signal level in the absence of any metabolic inhibitor or uncoupler) [18].

G. COMPLEX I AND II ASSAYS

For a separate sets of normoxic and hyperoxic lungs the activities of mitochondrial complex I and II were determined as previously described [21], [22]. Briefly, lungs were isolated and washed free of blood with perfusate containing (in mM) 4.7 KCl, 2.51 CaCl₂, 1.19 MgSO₄, 2.5 KH₂PO₄, 118 NaCl, 25 NaHCO₃, 5.5 glucose, and 2.5% Ficoll. Lungs

were then removed from the perfusion system, weighed, minced, and homogenized with buffer (pH 7.2) containing (in mM) 225 mannitol, 75 sucrose, 5 3-[N-morpholino] propanesulfonic acid, 20 ethylene glycol-bis (B-aminoethyl ether)-N,N,N',N'-tetraacetic acid, 2% fatty-acid free BSA, and 0.02 ml per ml protease inhibitor cocktail set III (Calbiochem, La Jolla, CA), utilizing a Polytron tissue homogenizer. Lung homogenates were centrifuged at 1,500 g for 5 min at 4 °C, and the resulting supernatants were centrifuged again at 13,000 g for 30 min at 4 °C to obtain a crude mitochondrial fraction (P2). The P2 fractions were washed twice by resuspension in 8 ml ice-cold homogenization buffer without BSA and then centrifuged (13,000 g for 20 min at 4 °C). The final P2 fractions were resuspended in 1-ml BSA-free homogenization buffer. Mitochondrial complex I (NADH dehydrogenase) activity (nmol NADH oxidized · min⁻¹ · mg protein⁻¹) was determined as the difference between the rates of NADH oxidation in the presence and absence of rotenone over the linear portion of the reaction progress curve as we have previously described [21]. Mitochondrial complex II (succinate-coenzyme Q reductase) activity was determined as the difference between the rates of reduction of the artificial electron acceptor 2,6-dichlorophenolindophenol (DCPIP) in the presence and absence of thenoyltrifluoroacetone (TTFA, complex II inhibitor) over the linear portion with succinate as donor [22]. The protein concentrations were determined colorimetrically as previously described [21].

H. STATISTICAL EVALUATION OF DATA

Data are presented as means ± standard error (SE) unless otherwise stated. Statistical comparisons were carried out in each group using paired and unpaired *t*-test as appropriate for design, with *p* < 0.05 as the criterion for statistical significance.

III. RESULTS

Rats did not display any sign of distress after 48 hours of exposure to >95% O₂. Over the course of this exposure period, the rats experienced a small (~3%), but significant loss in body weight (pre- and post-body weights of 337 ± 14 (SE, *n* = 16) g and 327 ± 13g, respectively). Histology revealed preserved lung morphology after 48 hours of hyperoxic exposure (Fig. 3).

For both normoxic and hyperoxic lungs, the response of both NADH and FAD lung surface signals to lung perfusion with rotenone, KCN, or PCP appeared within a minute of adding the chemical to the perfusate reservoir (Fig. 4 and fig. 5). An increase (from baseline) in NADH fluorescence signal indicates reduction of the mitochondrial matrix (Fig. 2), whereas an increase in the FAD fluorescence signal indicates oxidation of the electron transport chain. In this paper, the change in NADH signal in the presence of rotenone or KCN is considered a measure of mitochondrial complex I activity, and the change in the FAD signal in the presence of KCN is considered a measure of mitochondrial complex II activity.

FIGURE 3. Histology: Images of H&E section of normoxic (a) vs. hyperoxic (b) lungs. After 48 hours of exposure, lungs show no evidence of neutrophilic infiltrates, pulmonary edema, or vascular smooth muscle thickening, which are characteristic of hyperoxic injury sustained after rat exposure for 60 hours or longer.

FIGURE 4. Representative fluorometer response to perfusion with chemical inhibitors and uncouplers in a normoxic lung.

For normoxic lungs (Fig. 4 and Table 1), lung perfusion with rotenone (complex I inhibitor) reduced the mitochondrial matrix (ETC) upstream from complex I resulting in an increase in NADH signal by 20.2 ± 2.3 (SE) %, with no effect on FAD signal. Lung perfusion with KCN (complex IV inhibitor) reduced the ETC resulting in a 21.7 ± 2.5 %

FIGURE 5. Representative fluorometer response to perfusion with chemical inhibitors and uncouplers in a hyperoxic lung.

TABLE I. The effects of metabolic inhibitors and uncoupler on the lung tissue surface FAD and NADH fluorescence signals of normoxic and hyperoxic rats.

Inhibitor/ Uncoupler	FAD %		NADH %	
	Normoxic	Hyperoxic	Normoxic	Hyperoxic
Rotenone	0.2 ± 0.2	-0.3 ± 0.3	20.2 ± 2.3	7.5 ± 1.0*
KCN	-6.8 ± 1.6	-5.2 ± 0.5	21.7 ± 2.5	9.2 ± 1.2*
PCP	1.7 ± 0.8	-2.3 ± 1.4*	-19.7 ± 2.1	-20.8 ± 1.2
PCP + KCN	-9.3 ± 1.0	-4.2 ± 0.7*	25.7 ± 2.6	9.0 ± 1.0*
Rotenone + KCN	-3.3 ± 0.8	-3.8 ± 0.6	4.6 ± 1.0	2.8 ± 1.2

Values are mean ± SE. For the (PCP + KCN) and (rotenone + KCN) treatments, the percentage change due to additional treatment with KCN is calculated relative to the new baseline in the presence of PCP or rotenone, respectively. For normoxic lungs, n = 5, 7, 6, 6, and 5 for rotenone, potassium cyanide (KCN), pentachlorophenol (PCP), PCP + KCN, and rotenone + KCN, respectively. For hyperoxic lungs, n = 4, 5, 6, 5, and 4 for rotenone, KCN, PCP, PCP + KCN, and rotenone + KCN, respectively. * indicates value significantly different from the corresponding normoxic value (t-test, P < 0.05).

increase in NADH and 6.8 ± 1.6 % decrease in FAD. Lung perfusion with PCP, which uncoupled ETC from phosphorylation, decreased NADH signal by 19.7 ± 2.1% with no effect on FAD signal. The addition of KCN to PCP-treated lungs reversed the effect of PCP on the redox status of the ETC, increasing NADH signal by 25.7 ± 2.6% and decreasing FAD signal by -9.3 ± 1.0%. In the presence of rotenone, KCN resulted in a small but significant decrease (-3.3 ± 0.8%) in lung surface FAD signal and increase (4.6 ± 1.0%) on NADH signal as compared to values in the presence of rotenone only.

For hyperoxic lungs (Fig. 5, Table 1), lung perfusion with rotenone increased NADH signal by 7.5 ± 1.1%, which is 63% lower than in normoxic lungs, with no effect on FAD signal. Lung perfusion with KCN increased NADH by 9.2 ± 1.2%, which is 58% lower than in normoxic lungs. KCN effect on FAD signal in hyperoxic lungs was not significantly different from that in normoxic lungs. Lung perfusion with PCP had the same qualitative and quantitative effects on NADH and FAD signals as in normoxic lungs. The addition of KCN to PCP-treated hyperoxic lungs increased NADH by 9.0 ± 1.0%, which is 65% smaller than that in normoxic lungs. Furthermore, KCN decreased FAD signal by 4.2 ± 0.7%, which is 55% smaller than in normoxic lungs. These results are consistent with a more reduced chain upstream

TABLE II. Mitochondrial complex I and complex II activity measured in p2 fractions of lung homogenate.

	Complex I (nmol/min/mg protein)	Complex II (nmol/min/mg protein)
Normoxic	37.6 ± 3.2	79.1 ± 5.9
Hyperoxic	8.6 ± 0.7*	28.5 ± 2.3*

Values are mean ± SE. n = 4 and 3 for normoxic and hyperoxic lungs, respectively. * indicates value significantly different from the corresponding normoxic value (p < 0.05; t-test).

from complex I and II in hyperoxic lungs as compared to normoxic lungs, and suggest a decrease in complex I and II activities in hyperoxic lungs.

Because the data in Table 1 suggested that the hyperoxic exposure decreased complex I and II activities, we measured the activities of complex I and II in the P2 fractions obtained from lung homogenates. Table 2 shows that complex I and II activities normalized to protein were ~77% and 63% lower, respectively, in P2 fractions derived from hyperoxic than those of normoxic lungs.

IV. DISCUSSION

This paper demonstrates the utility of optical fluorescent imaging for evaluating the effect of subacute rat exposure to hyperoxia on the redox state of lung tissue mitochondrial electron transport chain (ETC) in a non-destructive manner in isolated perfused lungs. The results suggest a hyperoxia-induced decrease in complex I and II activities, and demonstrate the ability of this approach to detect a change in mitochondrial redox state in the early phase of hyperoxic lung injury, when histology is not different from that of normoxic rats.

A. NADH SIGNAL AND COMPLEX I ACTIVITY

Surface fluorometry results establish that rat exposure to >95% O₂ for 48 hours decreased the change in NADH signal in the presence of KCN or rotenone by 58% and 63%, respectively, as compared to those of normoxic lungs. A similar decrease (65%) in NADH signal was also measured following the addition of KCN to PCP-treated hyperoxic lungs as compared to normoxic lungs. Rotenone- or KCN-induced change in NADH signal is a measure of complex I activity. Thus these result suggest that the ETC upstream from complex I is more reduced in intact hyperoxic lungs than in normoxic lungs, and that complex I activity is lower in hyperoxic lungs. This is consistent with the 77% decrease in mitochondrial complex I activity per mg protein which we measured in P2 fractions derived from hyperoxic lungs as compared to normoxic lung.

The measured hyperoxia-induced change in complex I redox state (Table 2) could be due to a change in complex I protein and/or change in rate of NADH production. The latter could result from impairment to the Krebs cycle and/or change in cytosolic NADH/NAD⁺ which could affect mitochondrial NADH level via the malate-aspartate shuttle. However, the hyperoxia-induced change in complex I redox state

is most likely due to a change in complex I protein since for the complex I assay (P2 fraction), the NADH concentration used was the same for both normoxic and hyperoxic lung mitochondrial preparations (P2 fractions). The results of this assay (Table 2) show that the measured hyperoxia-induced change in complex I activity is qualitatively and quantitatively consistent with the hyperoxia-induced change in complex I redox state measured on the surface of the lung (Table 1).

The sulfhydryl-containing Krebs cycle enzymes pyruvate and alpha-ketoglutarate dehydrogenase and their coenzymes CoA and lipoic acid are sensitive to oxidative stress [23]. Previous studies evaluated the effect of rat exposure to 100% O₂ for 24 hrs on these and other Krebs cycle enzymes [15], [23], [24]. Gardner *et al.* [24] reported a 73% decrease in lung aconitase activity after 24 hrs of rat exposure to 100% O₂. This decrease is consistent with the increase in citrate level (aconitase substrate) in lung tissue under the same exposure conditions as reported by Bassett *et al.* [23]. This impairment to the Krebs cycle could affect NADH supplied to the electron transport chain and in turn complex I redox state. However it is not known whether this impairment to aconitase activity persists after 48 hrs of exposure to 100% O₂ or whether it is sufficient to account for the measured hyperoxia-induced change in complex I redox state. In another study, Bassett *et al.* [15] reported that rat exposure to 100% O₂ for 24 hrs had no effect on the activities of the Krebs cycle enzymes succinate dehydrogenase, isocitrate dehydrogenase or α -glycerophosphate dehydrogenase. In the present study we report a 64% decrease in succinate dehydrogenase (complex II) activity after 48 hrs of exposure to 100% O₂. Additional studies would be needed to evaluate the effect of rat exposure to 100% O₂ for 48 hrs on the activities of Krebs cycle enzymes isocitrate dehydrogenase, α -glycerophosphate dehydrogenase, and aconitase to determine the potential contribution of impaired production of NADH by the Krebs cycle to the measured change in complex I redox state.

Fisher AB [16] reported that rat exposure to 100% O₂ for 48 hrs increased lung lactate production rate (78%) and lactate to pyruvate ratio (108%). Since lactate to pyruvate ratio is proportional to cytosolic NADH/NAD⁺, the increase in lactate to pyruvate ratio suggests an increase in cytosolic NADH transported to the mitochondria matrix via the malate-aspartate shuttle. This shuttle provide more cytosolic NADH to mitochondria when the cytosolic NADH/NAD⁺ is higher than in the mitochondrial matrix. Thus the hyperoxia-induced increase in cytosolic NADH/NAD⁺ could contribute to the measured change in complex I redox state in hyperoxic lungs.

Rat exposure to hyperoxia had no effect on the change in NADH signal in the presence of PCP as compared to that in normoxic lungs as a measure of the coupling between ETC and phosphorylation. This observation implies that rat treatment with hyperoxia (>95% O₂ for 48 hours) did not alter the coupling between respiration and phosphorylation in lung tissue despite the apparent decrease in complex I activity. However, since the ETC upstream from complex I is more reduced

in hyperoxic lungs than in normoxic lungs, one would expect a larger PCP-induced decrease in NADH signal in hyperoxic lung. Currie *et al.* demonstrated that rat exposure to 100% O₂ for 48 hours decreased ADP-stimulated O₂ consumption (state 3) by ~50% with α -ketoglutarate as an NAD-linked substrate [25]. Together these results support a decreased tightness of coupling between respiration and phosphorylation in hyperoxic lungs as compared to normoxic lungs.

There is ample evidence that increased production of reactive oxygen species (ROS) is a major pathophysiological factor in the genesis of hyperoxic lung injury [3], [26]–[28]. Thus, one strategy that cells may have evolved to protect against hyperoxic lung injury is to mitigate the activities of ROS sources [12], [29]–[31]. Mitochondrial electron transport complex I is a major source of ROS [3], [27], [32]. Moreover, studies have shown that the rate of ROS formation at complex I in endothelial cells increased with an increase in O₂ tension, and that complex I inactivation using rotenone decreased ROS generation in sheep pulmonary microvascular endothelial cells exposed to hyperoxia (100% O₂ for 30 min) [27], [32], [33]. Thus the measured decrease in complex I could be an adaptive mechanism by the cells to decrease the rate of ROS formation at complex I under hyperoxic conditions.

On the other hand, the measured decrease in complex I activity could represent hyperoxia-induced injury leading to increases in the rate of ROS formation. Mitochondrial DNA (mtDNA) is highly sensitive to ROS [34]. Hyperoxia-induced increase in the rate of ROS formation could damage mtDNA and as a result compromise complex I activity since 7 out of 45 subunits of complex I are encoded by mtDNA [34], [35]. Hyperoxia-induced increase in ROS formation could also cause direct damage to complex I activity by oxidizing cardiolipin, which is sensitive to ROS [36], [37]. This phospholipid is important for the function of complex I [38]. In addition, oxidation of this lipid could lead to increase in the loss of electrons at complex I and in the rate of mitochondrial superoxide formation at complex I [36], [37].

Ratner *et al.* demonstrated that exposure of neonatal mice to hyperoxia (75% O₂ for 72 hours) decreases complex I activity in lung homogenates by ~70%, and that this decrease compromises mitochondrial oxidative phosphorylation and contributes to alveolar development arrest [7]. Fisher AB [16] showed that rat exposure to 100% O₂ for 48 hours had no effect on lung tissue ATP content as compared to normoxic lungs, although there was an increase (105%) in lactate/pyruvate ratio indicating an increase in ATP production via glycolysis. He suggested that the increased lactate/pyruvate ratio could be due to demand for glycolytic ATP and/or decrease in ATP production via oxidative phosphorylation which is compensated for by an increase in ATP production via glycolysis.

B. FAD SIGNAL AND COMPLEX II ACTIVITY

Compared to NADH, the measured change in the FAD signal in response to lung treatment with the metabolic inhibitors

was relatively small for normoxic and hyperoxic lungs (Table 1). One reason for this observation could be lower lung tissue concentration of FAD as compared to NADH. In fact, the FAD baseline signal is small relative to the NADH signal as evidenced by the difference in signal amplification for the NADH and FAD channels (10^3 for NADH compared to $\sim 6 \times 10^5$ for FAD) [18].

Lung treatment with KCN, which reduces the ETC upstream from complex IV, should reduce complex II and as a result decrease FAD signal. Just as a change in NADH tracks complex I activity, a change in FAD signal reflect complex II activity. Rat exposure to hyperoxia had no significant effect on the change in FAD signal in the presence of KCN as compared to that in lungs from normoxic rats. However, the change in FAD signal following the addition of KCN to PCP-treated lungs was 56% lower in hyperoxic lungs than normoxic lungs. It could be that lung treatment with PCP, which simulates the flow of reducing equivalents through the chain, fully oxidized the chain and as a result exposed the difference in the capacities of complex II between normoxic and hyperoxic lungs. Regardless, this apparent decrease in complex II activity is consistent with the 63% decrease in mitochondrial complex II activity per mg protein in P2 fractions derived from hyperoxic lungs as compared to normoxic lung (Table 2).

The measured hyperoxia-induced change in FAD signal in the presence of (PCP + KCN) could be due to a direct oxidant-induced inhibition of complex II or indirect inhibition of complex II by impairment of Krebs cycle enzymes/coenzymes that result in a decrease in succinate concentration or increase in the concentration of oxaloacetate (OAA). Complex II activity is inhibited by a high level of OAA. However the results of the mitochondrial isolates (P2 fractions) suggest that the hyperoxia-induced change in complex II redox state is most likely due to impairment of complex II itself since for this assay the concentrations of succinate and the electron acceptor (DCPIP) used were the same for the mitochondrial isolates from both normoxic and hyperoxic lungs and should be in excess of what is required for maximal function of complex II. The measured decrease in complex II activity using this assay (Table 2) is qualitatively and quantitatively consistent with the measured hyperoxia-induced decrease in FAD signal in the presence of PCP + KCN as a measure of complex II activity (Table 1).

Complex II is the only ETC complex that is completely encoded by nuclear DNA [39]. Hence, damage to mtDNA due to hyperoxia-induced increase in the rate of ROS formation should have no effect on complex II. Since electrons channeled through complex II produce 4-fold more mitochondrial superoxide than electrons channeled through complex I [40], the apparent decrease in complex II activity could be a means by the cells to reduce ROS formation under hyperoxic conditions.

Additional studies are needed to evaluate the effect of the depression in complex I and complex II activities observed in hyperoxic lungs on ROS production at complex I and III

and mitochondrial bioenergetics, and to determine whether this depression is an injury or an adaptive response to the hyperoxic environment.

C. SOURCES OF NADH AND FAD SURFACE FLUORESCENT SIGNALS

Our assumption in this paper is that changes in the mitochondrial pool of NADH is a key contributor to the measured changes in the NADH fluorescence signal since the metabolic inhibitors we used target the mitochondrial electron transport chain [18]. Another source of NADH signal is the cytosolic pool of NADH. Fisher *et al.* [41] demonstrated that rat lung treatment with KCN increased lung lactate/pyruvate by 4-fold. In this paper, lung perfusion with KCN increased lung surface NADH signal by 22% in normoxic lungs. Since lactate/pyruvate ratio reflects cytosolic NADH/NAD⁺ [42], [43], this suggests that cytosolic NADH did not contribute significantly to the measured lung surface NADH signal.

Unlike the NADH signal which has cytosolic and mitochondrial components, the FAD signal derives only from the mitochondria [18], [44]. Sources of redox-sensitive flavoprotein (FAD) include succinate dehydrogenase (complex II), lipoamide dehydrogenase (LipDH), and electron transfer flavoprotein (ETF) [18], [45], [46]. However, as previously discussed, most of the measured lung surface FAD signal is from complex II flavin [18].

Fisher AB demonstrated that rat exposure to 100% O₂ for 48 hours stimulated glycolysis as measured by $\sim 105\%$ increase in the lung lactate/pyruvate ratio [16]. Since this ratio is a measure of cytosolic NADH/NAD⁺, this suggest that lung tissue cytoplasm is more reduced in hyperoxic lungs than normoxic lungs. Thus, coupled with the results of the present study, the data document that both tissue cytosolic and mitochondrial compartments are more reduced in hyperoxic lungs than normoxic lungs.

The hyperoxia-induced decrease in complex I and II activities in the present study represents a relatively early *in situ* metabolic consequence of hyperoxia in that it precedes effects on lung histology, hemodynamic and functional endpoints observed with rat exposure to $>95\%$ O₂ for >48 hours [8], [47]. Of the few studies evaluating the metabolic consequences of hyperoxia in the 18-48 hr period, a decrease in serotonin clearance and an increase in lactate production have been observed in lungs from rats exposed to 100% O₂ for 18 and 36 hrs, respectively [16], [48]. Audi *et al.* reported that rat exposure to hyperoxia (85% O₂ for 48 hours) results in 47% decrease in the capacity of complex I mediated coenzyme Q₁ (amphipathic homolog of ubiquinone) reduction on passages through the pulmonary circulation as compared to that in lungs of normoxic rats [11]. Additionally, Klein *et al.* demonstrated a decrease in the metabolism of prostaglandin E₂ metabolism in intact lungs of rats exposed to $>97\%$ O₂ for 36 hrs [49].

D. LIMITATIONS AND POTENTIAL SOLUTIONS

In the present study and previous studies by us and others [18], [50]–[52], the relative change in the NADH and FAD

signals are reported instead of the actual signals which are sensitive to various factors including probe distance from the organ surface, day-to-day variations in light intensity, and PMT gain settings. One approach to overcoming this limitation would be by imaging a phantom of known NADH and FAD concentrations at the end of a given experiment (lung), and then using this information to scale the measured NADH and FAD signals. This would allow us to compare unnormalized signals from different lungs.

The lung surface optical imaging data do not provide information about the specific types of lung cells contributing to the measured NADH and FAD signals, although endothelial cells would be expected to contribute significantly because of their relatively large surface area and fraction of total lung cells [8]. Though determining the contributions of specific lung cell types to the measured signal is potentially important, the global oxidoreductive state of the lung tissue is a highly valuable piece of information irrespective of the individual cell types contributing to the redox ratio.

Another limitation of lung surface optical imaging is that it *may* not detect deeper than 500 μm , with a diameter of 3.2 mm, for a volume of $\sim 4 \text{ mm}^3$. However, this resolution is more than sufficient for determining the RR of parenchymal tissue which has a thickness (air to plasma) of 1.6 μm [8]. That said, central lung lesions without pleural extension would not be expected to be detected by surface fluorescence measurements such as those used in the present study.

V. CLINICAL AND TRANSLATIONAL SIGNIFICANCE

Over 900,000 adults receive invasive mechanical ventilation (MV) in the United States each year [53], [54]. Many either have acute lung injury (ALI) or have conditions such as shock and severe sepsis that place them at particular risk of ALI [54]–[59]. Treatment with high fractions of oxygen to maintain adequate tissue oxygenation may further exacerbate lung injury. However susceptibilities to lung injury (from hyperoxia or shock) are widely variable from person to person, and there are only crude means of screening for or following these injuries clinically.

The results of this paper suggest that hyperoxia-induced mitochondrial dysfunction occurs prior to the inflammatory phase of lung O_2 toxicity. If so, a change in lung surface mitochondrial redox state measured using optical fluorescence techniques could be used as an index of lung O_2 toxicity in patients with ALI requiring high oxygen therapy or to monitor the progression of ALI and its most severe form Acute Respiratory Distress Syndrome (ARDS), one of the most frequent causes of admission to the intensive care unit [60]. The fiber optic probe could be placed on the lung pleural surface through a small thoracotomy incision or a thoracostomy tube in patients with these devices in place. Alternatively, the probe might be introduced through an endotracheal tube, and positioned against airway epithelium. The same probe could be used to evaluate the efficacy of novel or existing interventions on lung tissue mitochondrial redox state and energy homeostasis in real time.

An individual with enhanced susceptibility to ARDS would be a strong candidate for strategies such as scrupulous attention to ventilation with low tidal volumes, deliberate tolerance of lower arterial oxygen or higher carbon dioxide tensions to limit oxygen toxicity or barotrauma, avoidance of transfusions, etc [53]–[59]. These interventions decrease injury but incur additional risks (increased sedation, impairment of vital organ function) that limit their universal and strict application in ALI patients.

The diagnostic and therapeutic monitoring applications of this tool are important not only for ALI/ARDS, but also for other lung conditions including lung cancer which is characterized by mitochondrial impairment (so called Warburg effect) [61], lung transplant related ischemia-reperfusion injury [62], or other animal models of human ALI [63]. Additional applications include diagnostic and therapeutic monitoring of conditions in other organs with high energy flux such as heart ischemia-reperfusion injury and heart failure management, or intraoperative identification of ischemic intestine and others [64]–[66].

ACKNOWLEDGMENT

We appreciate the technical help from R. Bongard, and input from Dr. M. Merker in the C. J. Zablocki VA, Milwaukee, WI.

underlying mechanisms of acute lung injury.

SAID H. AUDI is an Associate Professor of biomedical engineering with Marquette University. His research interest has been primary in mathematical modeling of physiologic systems, including in the areas of pulmonary mass transfer, pulmonary hemodynamics, and functional imaging. His research focuses on using indicator dilution techniques, optical fluorescence and single photon emission computed tomography imaging, as well as computational modeling to elucidate the

He is currently a Software Engineer with Prairie Technologies, Inc., Middleton, WI, USA.

KEVIN S. STANISZEWSKI received the B.S. degree in electrical engineering from the University of Wisconsin Milwaukee, Milwaukee, WI, USA, in 2009, and the M.S. degree in electrical engineering with the same university. He began working in the industry with a Test Engineer Internship at Cooper Power Systems in 2009. After finishing his graduate studies, he continued to work as a Research Associate in the Biophotonics Laboratory, University of Wisconsin Milwaukee.

states.

STEVEN T. HAWORTH is a Research Scientist of pulmonary and critical care medicine with the Medical College of Wisconsin and Research Engineer at the Zablocki VA Medical Center. His interests focus on using a range of medical imaging modes (microcomputed tomography, micro single-photon emission computed tomography) as tools for understanding the overall structural, functional and metabolic relationships of the pulmonary vascular system under various compromised diseased

ELIZABETH R. JACOBS is a Professor of pulmonary and critical care medicine at the Medical College of Wisconsin and the Associate Chief of Staff at the Zablocki VA Medical Center. Her interest is in mechanisms underlying acute lung injury as well as novel diagnostics to better identify pulmonary injury.

MAHSA RANJI is an Assistant Professor with the Electrical Engineering Department, University of Wisconsin-Milwaukee, Milwaukee, WI, USA. She is the Director of the Biophotonics Laboratory with research focus on optical imaging, and image processing of tissue metabolism. Her group has implemented optical devices to study cardiopulmonary injuries.

REYHANEH SEPEHR received the B.S. and M.S. degrees in biomedical engineering from the Amirkabir University of Technology, Tehran, Iran, and is currently pursuing the Ph.D. degree with the Electrical Engineering Department, University of Wisconsin, Milwaukee, WI, USA. Her research focus in Biophotonics Laboratory is on optical studies of the metabolic status of different tissues and mostly on signal and image processing techniques and algorithms.
