Abstract

To better understand the roles that hormones and experience play in infant survival and maternal behavior in a biparental primate species, we analyzed urinary estrone (E₁C) and pregnanediol glucuronide (PdG) from 24 socially housed titi monkey (*Callicebus cupreus*) females over 54 pregnancies (N = 1430 samples). Pregnancies were categorized according to whether the infant survived (N = 35) or not (N = 19), and by maternal parity (primiparous: N = 9; multiparous: N = 45). Mothers of infants that survived had a significantly greater drop in PdG from the third trimester to the first week postpartum than mothers of infants that did not survive. Multiparous mothers had a greater increase in PdG from the first to the third trimester as well as greater increases in the E₁C:PdG ratio from the first trimester to the third trimester and from the third trimester to the first week postpartum. There were positive relationships between third trimester PdG and maternal carrying and nursing during the first week postpartum, and between maternal age and carrying during the infant's first month of life. There was a negative correlation between maternal age and PdG during the third trimester. These results suggest that elevated progesterone during late pregnancy followed by progesterone withdrawal immediately following parturition is associated with greater probability of infant survivorship and maternal behavior in this species, and that older females engage in more postpartum maternal care.

Keywords

steroid hormones; maternal behavior; maternal parity; infant survival

INTRODUCTION

Steroid hormones, including estrogen (E) and progesterone (P), during late pregnancy originate from multiple organs and serve multiple functions. The primary sources of these hormones include the mother, the fetus, and the placenta, and the main purpose of the hormones is to facilitate communication between these three sources so as to orchestrate a successful gestation [Chambers and Hearn, 1985; Godfrey, 2002; Haig, 1996; Rutherford,

2009]. An additional function of these hormones that has evolved in mammalian lineages is to prepare females for labor, birth, and maternal behavior following birth. Of particular interest to this study is whether these hormones appear to influence maternal care and, ultimately, infant survival, and whether female parity predicts their concentrations in a monogamous nonhuman primate.

E concentrations, which peak before the onset of labor [Moltz et al., 1970; Terkel and Rosenblatt, 1972; Yoshinaga et al., 1969], have been associated with the initiation of maternal behaviors in many mammalian species. Critically, E is most effective at initiating maternal behaviors when acting synergistically with other ovarian hormones. Moltz and colleagues [Moltz et al., 1970] experimentally induced maternal behaviors in ovariectomized nulliparous rat dams by administering estradiol (E₂), P, and prolactin at specific time points during gestation. The simultaneous withdrawal of P and stimulation by E are critical to initiating maternal behaviors [Hauser and Gandelman, 1985].

P primarily functions in creating a hospitable environment for the developing embryo. In most mammals, a drop in P immediately precedes the onset of labor [Brown et al., 2006], however, the drop is less dramatic in primates than in other species [Power and Schulkin, 2006]. Because of the critical role P plays during gestation and the events immediately leading up to parturition, several studies have investigated the role that this hormone may play in the initiation of maternal behaviors. In rats, treatment with estrogen induces maternal behaviors in virgin females [Siegel and Rosenblatt, 1975a], while simultaneous P treatment inhibits this behavioral change [Siegel and Rosenblatt, 1975b]. In ewes, vaginal stimulation is necessary to inhibit aggression towards offspring but is only effective following hormonal priming with E and P [Kendrick and Keverne, 1991]. In common marmosets, a more dramatic prepartum drop in P is associated with greater maternal motivation postpartum [Pryce, 1993]. However, in baboons, those mothers that had the greatest drop from prepartum pregnanediol glucuronide (PdG; a metabolite of P), to postpartum PdG maintained less contact with their infants—the exact opposite pattern observed in marmosets [Bardi et al., 2004]. In a study comparing rhesus and Japanese macaques, no differences in maternal style were associated with PdG [Bardi et al., 2003]. One possible explanation for the contrasting findings between marmosets, baboons, and macaques is that a critical factor in determining the role that PdG plays in initiating maternal behavior is the social system of the species. That is, PdG signaling may have a different meaning in a species that regularly engages in biparental care of offspring and a species in which care of offspring is nearly entirely achieved by females. Further, other hormonal profiles (e.g. oxytocin, estrogen, prolactin) of females in different social structures are very likely different, which could influence the expression, and subsequent urinary concentrations of PdG [Ramirez et al., 2004; Shively et al., 2007; Wilson et al., 2005].

Maternal parity, or the amount of maternal experience a female has, is also known to influence maternal care and, ultimately, infant survival in mammals. Generally, more maternal experience is associated with better maternal care [Epple, 1978; Hrdy, 1999; Maestriperi et al., 1997; Tardif et al., 1984]. This may be due to the following: increased physical fitness of the older mother leading to greater reproductive success [Cameron et al., 2000]; increased knowledge of how to successfully raise offspring leading to greater

reproductive success (e.g. [Fairbanks, 1996; Green, 1990]); and the initial gestation having “primed” the female to behave maternally resulting in multiparous females behaving appropriately, while primiparous females may not [Caraty and Skinner, 1999; Kendrick and Keverne, 1991; Keverne, 1996; Rosenblatt and Siegel, 1981].

The majority of research in this field has been conducted in either rodents or sheep. While these models have made many contributions to our current understanding of the role of neuroendocrine mechanisms in maternal behavior, behavioral and physiological differences exist between these taxa and those more closely related to humans. Perhaps the most relevant difference to this study is the fact that the endocrine patterns and the sources of certain gestational hormones differ between primates and other mammals [Power and Schulkin, 2006]. In most mammalian species P is converted to E₂ by the placenta. This means that elevations in P are followed by elevations in E₂ and reduction in P particularly in late term gestation when the placenta is most efficient [Smith et al., 2005]. In primates, the placenta is incapable of converting P to E₂ because it lacks the critical enzyme 17 α -hydroxylase-17,20-lyase [Kallen, 2004]. The source of E₂ accounting for the late gestation rise is conversion from Dehydroepiandrosterone sulfate (DHEAS) from the fetal adrenal gland. Thus, in primates, but not in rodents, late term elevations in E₂ do not result in obligatory decreases in P and both hormones can be simultaneously elevated [Rainey et al., 2004].

While nonhuman primates generally are more similar to humans than rodents, the majority of primate species are distinct from humans in their parental behaviors. That is, in most primate species, parental behavior comes exclusively from the mother, whereas human families have exhibited a wide range of parental styles throughout history, among them biparental care, which is the norm in modern Western culture [Feldman et al., 2010]. Titi monkeys (*Callicebus cupreus*) are particularly appropriate for modeling human parental behavior and its underlying physiology because they, like humans, exhibit social monogamy [Fuentes, 1998] and biparental care [Fragaszy et al., 1982; Mendoza and Mason, 1986]. Titi monkeys also exhibit dramatic variability in their expression of parental care. In most cases, the father is the primary carrier of infants, and the mother carries only for short periods of time to allow the infant to nurse [Mendoza and Mason, 1986]. As a result, the infant will only show an adrenocortical response to separation from its father, not from its mother [Hoffman et al., 1995]. In certain individuals, however, the mother is the primary, or even exclusive, carrier of the infant. The mechanisms that are responsible for these individual differences are not known, but if the behavioral similarities between titi monkeys and humans are driven by similarities in physiology, then titis would represent an ideal model to study the physiology underlying human parental care and could yield information about individual differences in parental care present in humans.

This study was designed to investigate the association between maternal hormones (estrogens and progestins), maternal experience, maternal behavior, and infant survivorship in a monogamous New World primate, the coppery titi monkey. We predicted that a greater peak in estrogens prior to parturition and a greater drop in progestins at parturition would result in a stronger expression of maternal behaviors and result in a greater likelihood of offspring survival. In addition, we predicted that mothers with previous experience rearing

offspring would have greater infant survival, a greater prepartum estrogen peak, and a more dramatic drop in progestins than inexperienced mothers.

METHODS

All procedures used in this study were approved by the University of California, Davis Institutional Animal Care and Use Committee, and adhered to the American Society of Primatologists (ASP) Principles for the Ethical Treatment of Non Human Primates and the legal requirements of the United States.

Subjects

Subjects were 24 coppery titi monkey (*Callicebus cupreus*) females housed at the California National Primate Research Center (CNPRC). All females had been raised, and at the time of the study were living, in family groups consisting of an adult male and female and their offspring, a social living condition that approximates the species typical pattern displayed in free-ranging titi monkeys. All females were sexually mature (mean age = 4.18; range: 2.8–6.4) and had been paired with a sexually mature male for at least one year. Aside from infrequent removal for health or experimental purposes all animals lived continuously with their mates and offspring during the study and were housed in cages (2.13 m × 1.27 m × 1.27 m), identical to the housing described previously [Mendoza, 1999]. Twice daily (at 0800 and 1300 hrs) titi monkeys were fed a diet consisting of monkey chow, cottage cheese, marmoset jelly, apples, raisins, baby carrots, and vitamins.

Sample collection and analysis

Urine samples were collected during the first morning void at 0600 hr once per week. Within 30 min of collection samples were transferred to polypropylene tubes and stored at –20°C until assay. Samples from the entire gestation (gestation length based on [Valeggia et al., 1999]) and the first three months post-partum were assayed for urinary concentrations of estrogen (E₁C) and progesterone (PdG) metabolites (1430 urine samples from 54 pregnancies). Most females were represented multiple times in the data set (mean number of pregnancies = 2.45; range: 1–6).

All urine samples were assayed via enzyme immunoassays (EIAs) for pregnanediol-3-glucuronide (PdG; [Monro et al., 1991]) and estrone-1-conjugates (E₁C; [Shideler et al., 1990]) that had been previously validated for titi monkeys [Valeggia, 1996]. All samples were assayed for creatinine (Cr) concentrations in order to correct hormone concentrations for diluteness of urine [Jaffe, 1886] and concentrations are reported as pg of hormone per mg Cr. Inter-assay coefficients of variance were 1.55% and 1.72% and intra-assay coefficients of variance were 0.89% and 2.39% for PdG and E₁C, respectively.

Behavioral analysis

One-hour video recordings were conducted for each female three times per week following the birth of her infant. Observations were one hour in length with the infant as the focal individual. Recordings were scored for maternal behaviors of interest included nursing, carrying (measured as duration), anogenital licking, investigation, and face licking

(measured as frequency; see Table I for description of behaviors). Video recordings were scored using Behavior Tracker v. 1.5 (www.behaviortracker.com) by individuals blind to the reproductive status of the females.

Infant weighing

Infants were weighed at six days of age. Following the initial weighing, weights were recorded every 14 days until the offspring reached nine months of age.

Statistical analyses

Infants were categorized as “surviving” if they survived to at least two weeks of age (survive = 35 infants; not survive = 19 infants). This survival rate (65.8%) is similar to that found in other New World monkey species [Tardif et al., 1984]. Infant mortality in this study was due to either developmental problems resulting in complications in gestation or insufficient communication between the infant and parents postpartum. Generally, early gestational complications resulted in either spontaneous abortion of the fetus or a stillborn infant, and late gestational complications resulted in insufficient communication between the infant and parents, and ultimately to parental rejection. In either case, the exact cause of infant death was often unknown.

Mothers were categorized as being multiparous if at least one previous offspring was confirmed alive at birth ($N = 45$ pregnancies). That is, she had at least one previous opportunity to behave maternally. This categorization excludes cases where the infant was found dead and we were unable to determine whether the infant was born alive or dead. Those females were considered primiparous ($N = 9$ pregnancies). Hormone concentration means were calculated for each female for each of her pregnancies if samples were obtained from multiple pregnancies.

Samples were categorized according to the time relative to parturition that they were obtained: first, second, and third trimester, and the 1st week postpartum. We used generalized linear mixed models (GLIMMIX macro in SAS 9.1) that controlled for maternal age and infant weight at first weighing, with maternal identity as a random factor, to investigate whether E_1C , PdG, or E_1C :PdG ratio were significant predictors of infant survival. In addition, we investigated maternal parity as a predictor of maternal E_1C , PdG, and E_1C :PdG ratio (Table II).

Correlations between hormone concentrations and maternal behaviors occurring in the same time period were calculated, as well as correlations between prepartum hormone concentrations and postpartum behaviors. Correlational analysis was used to determine if maternal hormones or behaviors were predictive of infant growth rate. Correlational analyses were used to determine if maternal age was associated with differences in maternal hormones and behaviors. In all correlation analyses the Hochberg-Benjamini false discovery rate (FDR) correction was used to adjust p-values for multiple tests [Benjamini and Hochberg, 1995]. Chi-square analysis was used to analyze proportions of surviving offspring between multiparous and primiparous mothers. T tests were used to compare infant growth rates across maternal parity.

RESULTS

Infant survival

Neither mean E₁C levels, nor mean PdG levels at any time point predicted infant survival (all *P*s > 0.25; Fig. 1A). However, the drop in mean PdG from the third trimester to the first week postpartum was significantly greater in mothers of surviving infants than mothers of infants that did not survive (Fig. 1B; $F_{1,22} = 4.87$, *P* = 0.04). There were no significant differences in the E₁C: PdG ratio at any time point, or across time points.

Maternal parity and age

Infants of multiparous mothers were more likely to survive than infants of primiparous mothers ($\chi^2 = 7.29$, *df* = 1, *P* < 0.01). Maternal parity was not predictive of E₁C at any time point, or of the change in E₁C across time points (all *P*s > 0.20; Fig. 2A). The change in PdG from the first to the third trimester was significantly greater among multiparous mothers (Fig. 2B; $F_{1,24} = 12.17$, *P* < 0.01). The increase in the E₁C: PdG ratio from the first trimester to the third trimester was significantly greater in multiparous mothers (Fig. 2C; $F_{1,21} = 30.33$, *P* < 0.01). Similarly, a significantly greater increase in the E₁C: PdG ratio was seen in multiparous mothers from the third trimester to the first week postpartum (Fig. 2C; $F_{1,28} = 83.36$, *P* < 0.01).

There were no significant differences in maternal behavior between primiparous and multiparous mothers. There were no differences between primiparous and multiparous mothers in infant growth rate (*P* = 0.37), infant weight at one week (*P* = 0.44), or infant weight at one month (*P* = 0.30). No significant correlations between infant growth rate and any maternal behaviors or maternal hormone concentrations were found (all *P*s > 0.18).

Maternal age was negatively associated with PdG during the third trimester ($r_{52} = -0.445$, *p* < 0.01). Maternal age among mothers of infants that survived was positively associated with carrying during the first week postpartum ($r_{21} = 0.464$, *p* < 0.05) and the first month postpartum ($r_{21} = 0.466$, *p* < 0.05). Maternal age did not differ significantly between mothers of infants who survived and mothers of infants that did not survive ($t_{52} = 0.123$, *p* = 0.90).

Maternal hormone X behavior correlations

No significant correlations were found between either E₁C or PdG and maternal behaviors measured within the same time period as the hormones were collected (all *P*s > 0.21). Significant positive correlations were found between third trimester PdG and maternal carrying during the first week (Fig. 3A; $r_{53} = 0.374$, *P* = 0.03) and maternal nursing during the first week (Fig. 3B; $r_{53} = 0.475$, *P* < 0.01).

DISCUSSION

The main objectives of this study were to investigate the association between maternal estrogens and progestins, maternal experience, maternal behaviors, and infant survivorship. E₁C concentrations were not associated with any maternal behaviors, nor did E₁C differ between primiparous and multiparous mothers or between mothers of infants that survived

and those that did not. Changes in PdG differed between pregnancies that resulted in surviving vs. non-surviving infants, and between multiparous and primiparous mothers. Although PdG concentrations at no single time point predicted infant survival, the drop in PdG from the third trimester to the first week postpartum was greater in mothers whose infants survived.

In female sheep central administration of P increases responsiveness towards infant signals and likelihood to perform maternal behaviors [Kendrick and Keverne, 1991; Wang et al., 1995]. We did not find differences in maternal behavior in the immediate postpartum period, but multiparous mothers showed a greater increase in PdG from the first to the third trimester, and multiparous females had greater rates of infant survival.

One mechanism by which P could influence maternal behaviors is through its impact on other neurotransmitter systems. P withdrawal following sustained elevations in P has been shown to increase oxytocin (OT) mRNA in the paraventricular nucleus of female rats [Amico et al., 1997; Blyth et al., 1997]. Central OT has long been implicated in the onset of maternal behaviors [reviewed in Insel and Young, 2001; Kendrick et al., 1987; Keverne, 1996], and steroid treatment enhances OT expression in both the magnocellular and parvocellular cells of the paraventricular nucleus (PVN) [Thomas et al., 1999]. A greater drop in P might result in increased OT expression, which is likely to have peripheral consequences in milk letdown [Saltzman and Maestripieri, 2011] as well as behavioral consequences [Champagne, 2008; Dwyer and Smith, 2008; Meddle et al., 2007]. The ability to provide milk to offspring is certainly critical to offspring survival in any mammalian species. Elevated P during late pregnancy followed by a dramatic decrease in P at parturition may also result in optimal *central* OT expression in the immediate postpartum and may be causally associated with maternal behavior and infant survival. However, this study was correlational in design, so we can not determine if hormones influenced survival and maternal behavior. It is equally possible that signals from the offspring, either *in utero* or postpartum, affected maternal hormone production. Further, maternal age or experience could influence her hormone profiles.

The hormones excreted by the mother may not necessarily originate from her tissues. These hormones are equally likely to have come from either the developing fetus or the placenta and may represent a mechanism through which the fetus communicates with the placenta [Albrecht and Pepe, 1999]. Higher pre-partum P affects not only the mother, but also the developing fetus, making the infant fully developed at parturition [Kleemann et al., 1994]. Therefore, if P can serve as a signal from the fetus and, in turn, can affect development of the fetus, differences in urinary PdG during gestation may represent differences in fetoplacental health [Kallen, 2004]. Although differences in urinary PdG during gestation were present, they do not appear to explain any variability in infant birth weights. A multitude of variables contribute to infant birth weight, and while PdG is a marker of developmental signalling, it seems in this case that other signals outweighed the effects of PdG [Chiesa et al., 2008; Goedhart et al., 2010].

Mothers with previous experience showed a greater increase in PdG from the first to third trimesters. While maternal parity was not predictive of E₁C, the increase in the E₁C:Pg

ratio was greater in multiparous mothers, both from the first to the third trimesters, and from the third trimester to the first week postpartum. High E₁C:Pg ratio during late pregnancy has been associated with initiation of maternal behavior and responsiveness in macaques [Bardi et al., 2001; Maestriperi, 1999]. Increased responsiveness towards infants may account for the increased survival rate of infants born to multiparous mothers as compared to primiparous mothers. Alternatively, we found a significant negative association between maternal age and Pg during the third trimester, as well as a negative association between maternal age and the drop in Pg from the third trimester to the first week postpartum. We also found a positive association between maternal age and carrying during the first week postpartum. Together these findings suggest that while maternal hormones may indeed influence behavior, maternal age may influence behavior as well – either directly through behavioral changes associated with aging not measured in this study, or indirectly through changes in hormonal profiles. Of particular interest here is that the negative relationship between maternal age and two measures of Pg concentration suggest that younger females have a “better” hormone profile, given that higher Pg during the third trimester and greater drops in Pg from the third trimester to the first week postpartum were observed in mothers of infants that survived. However, when the infant survives, older mothers engage in more maternal carrying of the infant.

The data presented here suggest that the decrease in maternal Pg from the third trimester to the first week postpartum is associated with increased infant survival. Additionally, this study provides evidence that differences in maternal parity and hormones are associated with differences in maternal behaviors and infant survival. While no causal relationship can be determined from this study alone, at least some of the mechanisms involved with the onset of maternal behavior and infant survival are similar to those that have been more thoroughly studied in rodents. As was previously mentioned, this species of monkey is fairly unique in that it is socially monogamous and engages in biparental care. Differences between this work and previous studies on this topic may provide insight into differences between monogamous and nonmonogamous primates in maternal behavior and the underlying physiology that drives that behavior. In addition, the patterns observed here may provide some understanding of the individual differences in parental care styles present in humans.

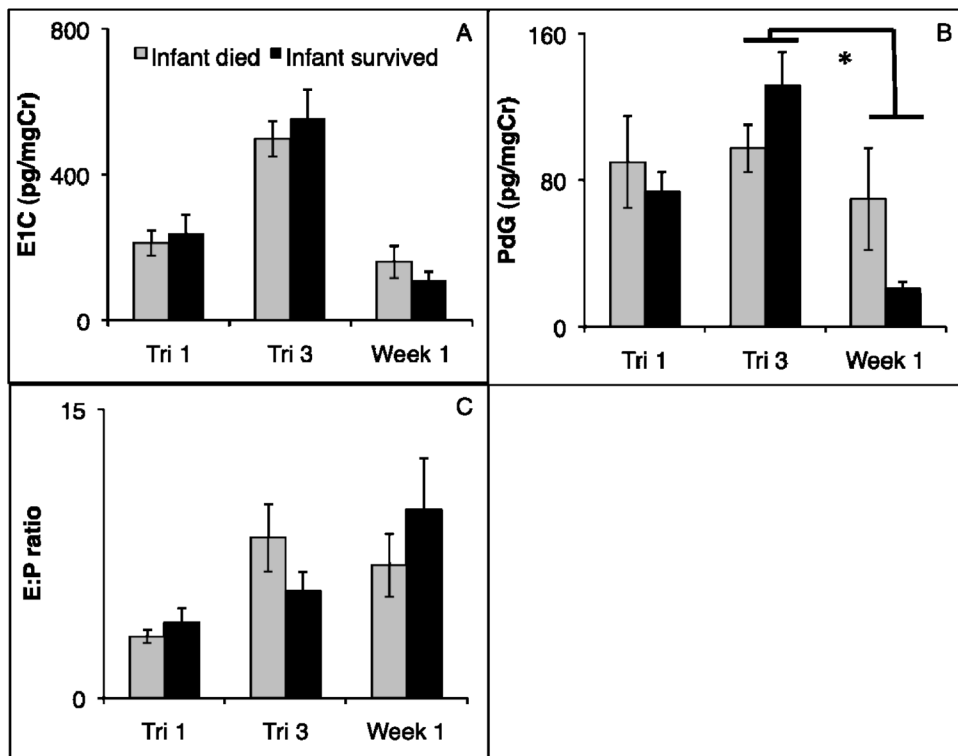

Figure 1.

E₁C (A), PdG (B) and E₁C:PdG ratio (C) averages at relevant time points (first trimester, last trimester, and first week postpartum) for mothers of infants that survived (dark) and mothers of infants that died (light). Mothers of infants that survived showed a greater drop in PdG from the third trimester to the first week postpartum ($* = p < 0.05$).

Figure 2. E₁C (A), PdG (B) and E₁C:PdG ratio (C) averages at relevant time points (first trimester, last trimester, and first week postpartum) for multiparous (dark) and primiparous (light) mothers. The increase in PdG from first trimester to third trimester was greater in multiparous mothers. E:P showed a greater increase in multiparous mothers, both in the change from first to third trimester, and third trimester to first week postpartum (* = $p < 0.05$ for change between time points between groups).

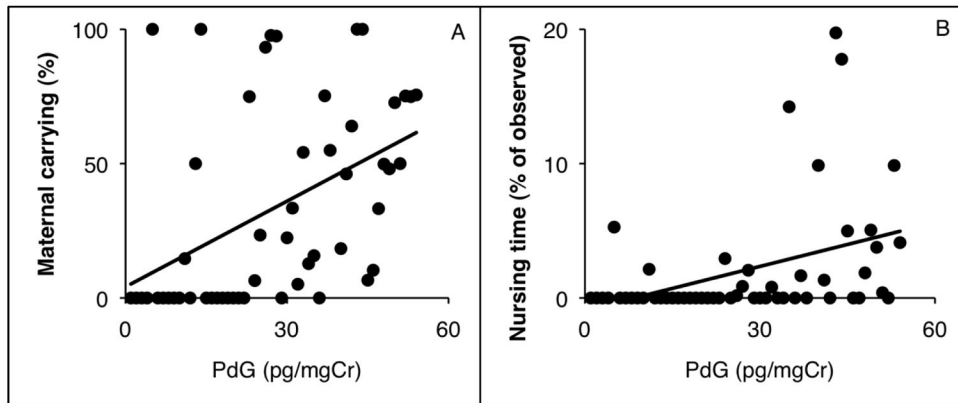

Figure 3.

Relationship between maternal PdG and maternal carrying (A) and nursing (B). PdG during the third trimester was associated with the percent of time the infant was observed being carried by its mother ($r_{53} = 0.374$, adjusted $P = 0.03$), and the amount of time the infant was observed nursing ($r_{53} = 0.475$, adjusted $P < 0.01$) as a percent of the total time observed during the first week postpartum.

Table IDescription of a number maternal behaviors typically expressed by *Callicebus cupreus*

Maternal behavior	Description
Carrying	Mother carries infant
Nursing	Infant observed in nursing position on mother
Anogenital licking	Mother licks anogenital region of infant
Investigation	Mother inspects infant, either while carrying or not
Face licking	Mother licks the face of the infant

Table II

Variables used in mixed models.

Dependent variable	Independent variables
Infant survival	Maternal hormones, maternal behaviors, maternal parity (controlling for maternal age, infant weight at one week).
Maternal hormones, maternal behaviors	Maternal parity, maternal age
Infant weight at one week [*] , infant weight at one month [*] , infant growth rate	Maternal parity, maternal hormones, maternal behaviors, maternal age
Nursing, week 1 Carrying, week 1	Maternal hormones

* Infant weight was only collected from infants that survived.

Table III

Summary of general linear mixed model significant statistics

Model	n	F-value	P-value
Infant survival			
Drop in maternal PdG from 3 rd trimester to 1 st week	23	4.87	0.038
Maternal parity			
Rise in PdG from 1 st to 3 rd trimester	24	12.17	0.002
Rise in E ₁ C:PgD ratio from 1 st to 3 rd trimester	21	30.33	<0.001
Rise in E ₁ C:PgD ratio from 3 rd trimester to 1 st week	28	83.36	<0.001
