Common visual problems in children with disability

Alison Salt, Jenefer Sargent

ABSTRACT

Children with disability are at a substantially higher risk of visual impairment (VI) (10.5% compared with 0.16%) but also of ocular disorders of all types, including refractive errors and strabismus. The aetiology of VI in children with disability reflects that of the general population and includes cerebral VI, optic atrophy, as well as primary visual disorders such as retinal dystrophies and structural eye anomalies. VI and other potentially correctable ocular disorders may not be recognised without careful assessment and are frequently unidentified in children with complex needs. Although assessment may be more challenging than in other children, identifying these potential additional barriers to learning and development may be critical. There is a need to develop clearer guidelines, referral pathways and closer working between all professionals involved in the care of children with disability and visual disorders to improve our focus on the assessment of vision and outcomes for children with disability.

INTRODUCTION

Visual impairment (VI) is relatively rare among childhood disabilities, with a cumulative incidence of severe VI (SVI) in the general population of 6 per 10 000 by 16 years of age; in over 75% of children, visual loss occurs in the context of significant non-ophthalmic impairments or disorders.¹ However, in children with complex or multiple disabilities, visual and indeed ocular problems are relatively common but may be overlooked as the focus may be on other aspects of health or management.^{2 3}

The higher prevalence of visual disorders in children with developmental disabilities is accounted for by the many underlying causes of their disability with prenatal and perinatal factors and acquired injury all of relevance. Therefore, visual disorders are particularly increased in children born preterm, children who have suffered brain damaging events with subsequent learning difficulty and/or cerebral palsy (CP) and children who have congenital cerebral anomalies or other genetic syndromes that may predispose to ocular anomalies. Children who have primary visual disorders may also be at risk of later disability.⁴

An overview of the various disorders that may affect the visual system in children with a disability is presented, with a focus on those at particularly high risk. Visual assessment can be challenging in this group of children and a practical approach to assessment will be outlined.

Definitions of VI and other terms are given in online supplementary appendix 1.

WHICH CHILDREN ARE AT MOST RISK OF VISUAL DIFFICULTY?**Children born preterm**

Children born preterm are at risk of brain injury, with periventricular leukomalacia (PVL), the most common brain lesion. Those who avoid major motor impairment are well known to be at risk of adverse developmental outcomes, including, for example, cognitive difficulty of variable degree, impairments in attention and executive function^{5 6}. It is less commonly recognised that they are also at risk of visual or ocular abnormalities. VI in children born preterm has been reported in between 1% and 3% with causes including cerebral VI and retinopathy of prematurity (ROP).⁷ Refractive errors have also been found to be four times more common in those born preterm (29.6%) than those born at term (7.8%)⁸ (table 1). These visual disorders result from both the 'premature exteriorisation' of the developing visual system and from the systemic complications of preterm birth.⁷

Holmström *et al*⁹ recently reported from a population-based follow-up study of 411 children born at <27 weeks' gestation, with only a minority having CP at 30 months' corrected age. Overall, a third had some type of eye or visual problem, most frequent in children previously treated for ROP (table 2).

Although hypermetropia is the most common refractive error in childhood, myopia is more common in those born preterm, occurring both in those with and without previous ROP. In those with strabismus, esotropia and exotropia are equally common, in contrast to full-term children in whom esotropia is three times as common as exotropia.⁷

Difficulties with higher-order processing of visual information may also occur and some authors have particularly highlighted the occurrence of such difficulties in children with PVL. Hard *et al*¹⁶ reported poor visual perceptual skills in almost half of a group of 51 children born before 29 weeks' gestation, only 6% of whom had PVL. Pagliano *et al*¹⁷ studied 24 children with spastic diplegia and PVL, 15 born prematurely and 9 at term. Those born preterm had poorer visual perceptual skills, suggesting that the PVL was not the key factor, but some other consequence of prematurity.

Children with CP

Premature birth and its sequelae are common precursors to CP and overlap exists between these two groups. Other causes of CP, including term hypoxic ischaemic encephalopathy, early brain malformations and congenital or postnatal infections, will also contribute to visual outcomes.

Data from UK and European CP registers indicate that up to 11% of children with CP are found

Table 1 Types of acuity measures used in children with disability

Type of measure	Principle of test and materials	Administration/response	Examples
Resolution: of spatial detail, for example, black and white lines	'Vanishing target'—target that is not resolved 'blurs' to background Child prefers to look at target that contains visual contrast	Child fixates target Tester blind to location of target and makes judgement of child's fixation Naming or pointing are not required	Keeler cards Teller cards Cardiff cards
Recognition	Some cognitive skill required—for example, matching	Child names or matches Matching usually achieved through pointing	Lea symbols Kay pictures Sonksen LogMAR test

to have SVI (acuity $<6/60$).^{12 18} A retrospective case series of 92 children with spastic quadriplegia from a single centre in Canada reported 20% with 'blindness'¹⁹ (not further defined).

A higher incidence of visual difficulties is generally seen in those with more severe motor impairment.^{20–22} However, visual difficulties are neither restricted to a single neurological or aetiological subtype of CP nor to acuity loss.^{20 21 23}

Ocular disorders including refractive error, strabismus and minor ocular abnormalities, not associated with significantly reduced acuity, also increased¹³ (table 2).

Very marked abnormalities of eye movement have also been found in children with CP, some of whom may have been previously described as 'blind'.^{24 25} Lesser degrees of oculomotor difficulty affecting both smooth pursuit and saccades have been described in children with all distributions of CP²⁶.

Children with CP can therefore be described as showing a range of neuro-ophthalmological abnormalities (reduced acuity, refractive errors, strabismus, oculomotor abnormalities and field alterations), which may be predictable according to the distribution of the motor impairment.²⁶

Children with PVL have also been found to have visuoperceptual difficulties that were not explained by acuity or cognitive impairments.^{27 28} These included weakness in visual object recognition, visuospatial skills, visual memory and oculomotor control.

Impairments of visual attention in children with CP have been described using a variety of terms, including 'fixation

impersistence', 'abnormal fixation', 'variable performance' and 'gaze dysfunction'.^{22 29 30} A complex relationship between visual attention, visuoperceptual difficulties and eye movements may exist. Children with very severe attentional difficulties are at risk of being misdiagnosed as 'blind' as they may not be able to achieve or maintain fixation during vision testing.

Visual outcomes following brain injury

Visual difficulty occurring in the context of a normal ocular exam is now generally termed cerebral (previously cortical) visual impairment (CVI). A number of different definitions of CVI exist,³¹ but most make reference to three criteria, namely a normal ocular examination, reduced visual acuity or subnormal visual performance and evidence of damage to the posterior visual pathways. While definitions are being clarified, it may be helpful to consider CVI as a 'spectrum' condition, in which not all possible consequences may manifest in each individual child or at all ages, for example, some aspects of perceptual dysfunction can only be identified in school-aged children.²⁷ It is also important to appreciate the other non-visual factors that can affect overall visual performance especially in very young children, such as cognitive or social impairment or positioning difficulties in children with severe movement difficulty.

Some children who experience brain injury show marked abnormalities of visual performance in the first year of life, which lessen over time. While improvement in visual function has been described as a characteristic of CVI, it is possible that

Table 2 Comparison of visual impairments in children with disability (as reported in some key studies)

Strabismus	27	–	25	59 ¹³	13.5–44 ^{8 9}	4–7.5 ^{14 15}

for some children this may simply reflect a slower than normal maturation of the visual system.

Children with learning difficulty

Several studies have reported an increased risk of VI in children with learning disability (LD).^{3 10 32} One of the most comprehensive population-based studies of children with borderline to profound learning difficulty, aged 4–15 years, found that the prevalence of VI was as much as 10 times higher than that described in general population-based studies¹⁰ (table 2).

The most common aetiologies of VI in studies of children with additional learning difficulties were CVI, optic atrophy, retinal dystrophies and congenital nystagmus.¹⁰ This is in line with the most common disorders described in the general population of children with VI.¹

Other more minor and potentially correctable visual disorders such as refractive disorders and strabismus also occur at higher frequency in children with LD (table 2)^{14 32}.

In children with LD, the prevalence of strabismus is most commonly reported to be between 21% and 27% (table 2) compared with up to 4% in typically developing children.¹⁵ Refractive errors and strabismus have also been found to be correlated with low IQ.¹⁴

Ophthalmological pathology has also been reported in 40% of patients with autism or related disorders, with 29% having significant refractive errors, 21% strabismus and 10% amblyopia.³³

Down syndrome

Trisomy 21 is one of the most common genetic disorders of childhood, and children with this disorder are at high risk of additional ocular disorders including refractive errors, reduced accommodation, strabismus, blepharitis, nasolacrimal duct problems, cataracts, congenital or acquired and keratoconus.^{11 34}

Maturation of acuity is often slower than in typically developing children and many children have slightly reduced visual acuity even when refractive errors are appropriately corrected.³⁵ There is also a high prevalence of strabismus among children with Down syndrome, independent of refractive error³⁶ (table 2).

Underaccommodation has also been found to be a substantial problem even when there is no, or a fully corrected, refractive error. This has important implications because near vision will be consistently out of focus for these children. Woodhouse has shown that children can benefit from provision of bifocal spectacles to compensate for poor accommodation.³⁷

Children with severe hearing impairment

Congenital rubella syndrome was previously the most common cause of dual sensory impairment in UK children but is now rare. Other congenital infections due to other infectious agents may have similar consequences.³⁸

CHARGE association, a genetic condition, is now the most common congenital cause of dual sensory impairment.³⁸ VI arises from ocular coloboma and is variable in degree. In severe cases, the eye can be rudimentary or anophthalmic; however, involvement is often asymmetrical. Retinal coloboma will also affect the visual field and will lead to severe acuity impairment if the macula or optic disc is affected. There is also an increased risk of retinal detachment and of corneal injury if there is incomplete eye closure.

Children with dual sensory impairment of any cause should undergo very careful evaluation of each sense.

Box 1 Developmental impact of visual impairment

Visual impairment affects the development of:

- ▶ spatial awareness, posture and movement skills
- ▶ use of hands and fine movement coordination
- ▶ early concept development, for example, object permanence
- ▶ locating sound in space
- ▶ understanding of the meaning of words and therefore speech and language development
- ▶ social interaction and communication
- ▶ self-care skills.

Primary visual impairment leading to disability

Vision integrates all other senses and therefore it is not surprising that SVI is known to constrain all areas of development in the early years of life. This is directly related to the level of vision loss (box 1).⁴

Development can be delayed by as much as 2 years in the first years of life and therefore specific developmental norms are available for children who are 'blind' and 'partially sighted'.³⁹ These delays can be overcome by the time children reach school age.

However, in children with profound VI (awareness of light or light-reflecting objects only) research has found that

Box 2 Assessment of ocular health and function (refraction, ocular movements, accommodation) and vision assessment

Current concerns and parent descriptions of everyday use of vision

Ocular exam

- ▶ observation for structural anomalies external, anterior and posterior segments of the eye
- ▶ observation for strabismus/squint
- ▶ eye movements—smooth pursuit *and* saccades
- ▶ *refraction—eye clinic—optometrist*
- ▶ *electrophysiological: electroretinogram and visual evoked potential if indicated—eye clinic.*

Assessment of vision

Detection vision

- ▶ If vision is severely reduced, aim to quantify with near detection scale.⁴⁰

Fixation

- ▶ quality: sustained, brief, uncertain
- ▶ fixation shifts: to objects presented

Visual recognition—(also elicited in history)

- ▶ faces
- ▶ objects
- ▶ pictures

Visual acuity

- ▶ behavioural measures:
 - resolution acuity—measured by preferential looking
 - recognition acuity—measured by matching or naming symbols or letters

Visual fields

- ▶ confrontation/modified distraction method
- ▶ *formal perimetry possible in older children—eye clinic*

approximately 30% of children are at risk of stasis or regression in cognitive development during the second year of life.⁴ Disordered social communication is most prominent in this group and the high level of autistic spectrum disorder in children who are blind is increasingly well recognised. This outcome is found even in children who have a primary visual disorder with no other obvious risk factors for brain vulnerability. It may be that there are as yet unknown genetic factors that contribute, but it seems likely that sensory deprivation plays a significant role in this serious developmental disorder.

Approach to identification of ocular or visual difficulty

Paediatric assessment of a child with disability should always include an ocular and visual assessment. Box 2 outlines a systematic approach. Potential visual difficulties can be identified through careful history taking (table 3), observation for ocular anomalies, eye movement difficulty (squint, nystagmus) or atypical visual performance. Assessment of fixing and following and near detection can be carried out in the clinic. Acuity can also be measured if tools are available (table 1).

Assessment of the child with disability should follow the same principles as that of any child, but adaptations may be necessary to take account of the child's developmental age and capacity to cooperate with more formal assessment. Therefore, knowledge of a child's developmental level is essential.

Children with severe physical disability may require adaptations to test administration and the preceding history should elicit descriptions of their usual response methods. A child must be comfortable and adequately positioned if optimal responses are to be elicited. Multidisciplinary assessment is helpful in building up a detailed picture of the impact of non-visual factors on the child's overall visual profile. An important principle of assessment is to gather information and objective observations before considering all possible explanations, both visual and non-visual, for the information gathered.

Any identified difficulty should prompt early referral to the eye clinic for more detailed ophthalmological examination including refraction, behavioural observations and acuity measurement with electrophysiology (measuring the integrity of the retina and visual pathways) where indicated. MRI may also assist in understanding the potential structural correlates of

visual function as well as the pattern of additional impairments or antecedent medical history.

If SVI is identified, a referral to the local Specialist Teaching team for children with VI should also be made. It is not necessary to wait for diagnostic confirmation if paediatric assessment indicates that severe visual difficulty is present.

History taking

Assessment always begins here and incorporates exploration of the current questions and concerns as well as detailed descriptions of the child's current visual skills. In some situations, the responses of children with additional disabilities may be interpreted according to hope, and beliefs about skills that may be based on an incomplete understanding of information received. For example, parents may previously have been told that their child's eyes are 'normal' leading to a belief that this guarantees normal vision. Careful enquiry as to whether the child's visual responses are predictable or variable and possibly dependent on other sensory modalities is vital, for example, is the child seeing or relying on hearing to respond to the stimulus.

Questionnaire approaches

To overcome some of the potential challenges of visual assessment in children with severe movement or other developmental difficulties, some authors have explored the usefulness of structured questionnaires. McCulloch *et al*⁴¹ developed a questionnaire to clarify visual skills in neurologically impaired children likely to have profound VI. Ferziger *et al*⁴² developed a questionnaire designed to document evidence of basic visual skills in children with multiple disabilities. Questionnaires to elicit possible manifestations of CVI have also been developed for use with children whose acuity is 6/60 or better.⁴³ However, it is important to appreciate that the role of some tools is to identify children who would benefit from further detailed history taking and assessment⁴⁴ and that some 'screening' questions may yield false positives⁴⁵ since some reported responses may be explained by other aspects of the child's disability.

Outcomes of assessment

Paediatricians are well placed to explain the consequences of any ocular abnormality or VI described by the ophthalmologist. For example, spectacles may be prescribed to correct refractive

Table 3 Parent history: current visual skills

*Does the child have a persistent asymmetric tonic neck reflex? Is there evidence that a particular head position is associated with minimisation of nystagmus? Can we be confident that the eye or head turning is definitely vision related or could they be spontaneous movements that are not in response to any stimulus?

†Ensure parents do not mean nystagmus, which is a wobbly movement or fast to and fro flickering.

error, though parents and professionals may need to understand that some children have additional, uncorrectable acuity reduction. Minor acuity reduction can be addressed through adaptation of visual material and advice about positioning within the classroom. For children with severe movement difficulty for whom vision can function as an important 'response mode',⁴⁶ the functional consequences of combined abnormalities of acuity, eye movement and attentional difficulties may best be understood by pooling all observations from the paediatric, therapy and educational teams.

Service provision

To meet the visual needs of children with disability, stronger links are needed between child development and community paediatric services, ophthalmology and specialist education services for children with VI. Some districts have a team with a special interest in vision who provide joint assessments and support links between all these services. The team may comprise a paediatrician, orthoptist, ophthalmologist (or have close links with a named ophthalmologist) and a qualified teacher for children with VI.

Some tertiary centres provide specialist assessment for children with VI. They can address questions that may be more challenging for local teams such as developmental questions in children with profound VI. Clinical judgements about this rare group of children require a breadth of experience that cannot usually be gained at secondary level.

Current practice: surveillance for children with disability at increased risk of ocular and visual disorders

Hall and Elliman⁴⁷ state the need for visual assessment of children with neurological impairment/CP, but in practice, assessment may be haphazard and abnormalities, which may in some children be severe, can be missed.^{2 48 49}

Studies of children with special needs have established that there are significant unmet visual needs in a high proportion of children, with one study reporting a fifth with SVI (legal blindness) who were undiagnosed.³ Woodhouse recently reported that half of a cohort of children attending special schools had refractive errors warranting new or first-time spectacle prescription.² These studies highlight the high level of potential unmet visual need in children with disabilities.

Although the full range of ocular and visual outcomes for children with learning difficulty, CP and other children with disability or at high risk of poor visual outcomes is well described in the literature, there are few agreed guidelines for routine assessment. School-based examination of children in specialist education has been recommended,² but local practice varies widely in the UK. For children with Down syndrome, clear guidelines have been published recommending monitoring for the onset of significant refractive errors and for strabismus regularly throughout early childhood. However, adherence to recommendations is variable.^{50 51}

How can practice be improved?

Closer working between professionals involved primarily in ocular and vision health and those working with children with disability would facilitate adherence to current guidelines and support identification of VI and potentially correctable vision difficulties in children who are known to be at high risk. In some child development teams (CDT), closer working is facilitated by an orthoptist working with the team. However, currently less than one-fifth of CDT have an orthoptist within the CDT (J Parr, personal communication, 2014).⁵²

Guidelines need to include routine ophthalmological assessment for children with severe hearing impairment and for those with severe physical disability who are highly dependent on active use of vision to support their communication and learning.³⁸ In addition, children with primary VI are at high risk of developing subsequent additional disability and therefore need intensive support and monitoring of development. The presence of even limited form vision appears protective, therefore visual promotion and support for families as early as possible is critical.⁴

Future developments

Vision is arguably the most important sensory modality underpinning child development and multiple professionals currently contribute to assessment of ocular structure and function and management of pathology. Assessment of *vision* itself can somehow be overlooked or at least not fully reported particularly in children with established disability. By contrast, children with suspected hearing impairment undergo dedicated and often repeated assessment of hearing by professionals whose specialism is audiology. While it may not be practical or even necessary to envisage a new speciality of 'visuology', the multi-disciplinary team, with the paediatrician at the centre, can nevertheless work more closely together to confirm the importance of detailed visual assessment that 'measures' acuity and assesses other vital aspects of ocular function and visual skill, and also provides practical, tailored guidance for the individual child.
