Abstract

Aim: To evaluate the performance of subjective evaluation of ultrasound findings (pattern recognition) to discriminate endometriomas from other types of adnexal masses and to compare the demographic and ultrasound characteristics of the true positive cases with those cases that were presumed to be an endometrioma but proved to have a different histology (false positive cases) and the endometriomas missed by pattern recognition (false negative cases).

Methods: All patients in the International Ovarian Tumor Analysis (IOTA) studies were included for analysis. In the IOTA studies, patients with an adnexal mass that were preoperatively examined by expert sonologists following the same standardized ultrasound protocol were prospectively included in 21 international centres.

Sensitivity and specificity to discriminate endometriomas from other types of adnexal masses using pattern recognition were calculated.

Ultrasound and some demographic variables of the masses presumed to be an endometrioma were analysed (true positives and false positives) and compared with the variables of the endometriomas missed by pattern recognition (false negatives) as well as the true negatives.

Results: IOTA phase 1, 1b and 2 included 3511 patients of which 2560 were benign (73%) and 951 malignant (27%). The dataset included 713 endometriomas. Sensitivity and specificity for pattern recognition were 81% (577/713) and 97% (2723/2798). The true positives were more often unilocular with ground glass echogenicity than the masses in any other category. Among the 75 false positive cases, 66 were benign but 9 were malignant (5 borderline tumours, 1 rare primary invasive tumour and 3 endometrioid adenocarcinomas). The presumed diagnosis suggested by the sonologist in case of a missed endometrioma was mostly functional cyst or cystadenoma.

Conclusion: Expert sonologists can quite accurately discriminate endometriomas from other types of adnexal masses, but in this dataset 1% of the masses that were classified as endometrioma by pattern recognition proved to be malignancies.

Key words: Ultrasonography, endometriosis, endometrioma, adnexal tumours, pattern recognition, subjective evaluation.

Introduction

The main benefit of an accurate preoperative classification of an adnexal mass as benign or malignant is that patients can be offered the best treatment strategy for their pathology, whether this involves expectant management, laparoscopy or debulking surgery by a gynaecologic oncologist in case of malignancy. To date, the best method described to discriminate between benign and malignant adnexal masses is the use of pattern recognition by an expert sonologist (Valentin *et al.*, 1999, 2001, 2004; Timmerman *et al.*, 2004). Pattern recognition is the subjective evaluation of the morphology and vascularity of the mass during an ultrasound examination (Valentin 2004). An increasing number of gynaecology centres have a specialised multidisciplinary team for endometriosis patients in order to give the patient the best treatment options. In particular, patients with severe and/or deep endometriosis may benefit from this strategy as every suboptimal attempt to excise endometriosis will create more fibrosis and adhesions making further surgery more complicated (Langgebekke *et al.*, 2006; Mereu *et al.*, 2007). Accordingly it is crucial that the preoperative assessment of an adnexal mass not only discriminates between the benign and malignant nature of a mass, but also correctly identifies the presence of endometriomas and the severity of endometriosis elsewhere in the pelvis (for example in the case of deep rectovaginal or vesico-uterine endometriotic nodules or a frozen pelvis) (Okaro *et al.*, 2006).

The aim of this study was to evaluate the diagnostic performance of pattern recognition to discriminate between endometriomas and other types of adnexal masses. A secondary aim was to describe the ultrasound characteristics of adnexal masses that 1° were presumed to be an endometrioma and on final histology proved to be an endometrioma (true positives) or 2° proved to have a different histology (false positives) as well as 3° the endometriomas that were missed by pattern recognition (false negatives).

Background

The underlying pathophysiology of endometriosis is not totally clear, but there is evidence that genetic factors are involved as well as molecular changes leading to an overproduction of oestrogen, prostaglandins and cytokines (Bulun *et al.*, 2009; Bischoff *et al.*, 2000; Campbell *et al.*, 2001; Kennedy *et al.*, 2003; Thomas *et al.*, 2000). However, there is controversy regarding the cellular origin of endometriosis (Bulun *et al.*, 2009). Spread of endometrial tissue by retrograde menstruation (“the implantation theory”) (Schenken *et al.*, 1989; Olive *et al.*, 1987) is one of

the hypotheses. The endometrial deposits would subsequently invaginate in the ovarian cortex resulting in endometriotic cysts or endometriomas. Another hypothesis is dissemination through lymphatic and blood vessels or metaplastic differentiation of the peritoneum (Dmowski *et al.*, 1994; Witz *et al.*, 2000).

Three forms of endometriosis are described: *peritoneal endometriosis* consisting of small implants on the peritoneal surface or external surface of the ovary, ovarian endometriotic cyst or *endometrioma*, and *deep endometriosis* affecting the ureters, bladder or rectovaginal wall and consisting of a conglomerate of endometriotic tissue, adipose tissue and fibrosis (Bulun *et al.*, 2009; Giudice *et al.*, 2004).

Epidemiology

Endometriosis occurs mostly in premenopausal women in the third decade of life. Estimating the true prevalence of endometriosis is difficult since most studies report on endometriosis in women that have undergone surgery and so had a confirmed histological diagnosis. The reported prevalence in fertile women is up to 20%, for patients undergoing a laparoscopy for pelvic pain it is between 20% and 50% and in the overall population it is estimated to be between 1 and 10% (Sangi-Haghpeykar *et al.*, 1995; Chatman *et al.*, 1982; Missmer *et al.*, 2004; Eskenazi *et al.*, 1997).

Symptoms

Almost 75% of the symptomatic patients report pelvic pain and dysmenorrhoea caused by active bleeding of the endometriotic tissue, production of cytokines and secondary development of adhesions (Sinaii *et al.*, 2008). Other symptoms are dyspareunia, abnormal bleeding and in case of deep rectovaginal or bladder nodes premenstrual dyschezia or mictalgia is reported (Sinaii *et al.* 2008; Kennedy 2005).

Tumor markers

Serum CA 125 is often elevated in patients with endometriosis and rises with increasing extensiveness of the disease (Cheng *et al.*, 2002; Mol *et al.*, 1998; Van Calster *et al.*, 2007). Increased CA-125 levels often cause anxiety, because because of their association with malignancies. CA-125 cannot be used as marker to identify endometriosis as the sensitivity and specificity are too low (Yang *et al.*, 2004).

Prognosis

The prognosis is usually good but the morbidity caused by the disease depends on the severity and

the degree of extraovarian spread affecting other organs. Adhesions formed by endometriotic tissue may result in reduced mobility of some organs such as the ovaries. Adhesions may also block the tubes and this may negatively affect fertility. Typically, patients with a history of infertility and a presumed sonographic diagnosis of adhesions or frozen pelvis are referred for surgery. The impact on fertility and the surgical treatment to improve fertility in patients with mild endometriosis, e.g. small peritoneal implants or a solitary endometrioma remains a matter of discussion although some reports indicate that laparoscopic resection or ablation of minimal and mild endometriosis enhances fecundity in infertile women (Marcoux *et al.*, 1997; Jacobson *et al.*, 2002; Lin *et al.*, 2005). Most experts believe that severe endometriosis in infertility patients should be surgically treated. Therefore, most patients undergo surgery when the endometrioma is more than 4 cm in diameter (Beretta *et al.*, 1998; Somigliana *et al.*, 2006). Unfortunately, surgery may also harm the vascularisation of the ovary or damage part of the ovarian cortex resulting in a decreased ovarian reserve. A further issue is that several studies highlight the potential risk of developing an endometrioid or clear cell carcinoma inside an endometrioma (Van Gorp *et al.*, 2004; Fukunaga *et al.*, 1997; Sampson 1925).

Macroscopy

Macroscopically, pelvic endometriosis is seen as small bluish nodules often with surrounding fibrosis. In the ovaries, lesions are commonly of a considerable size, are cystic and contain altered blood. Because of the dark colour of the cyst content, they are often referred to as 'chocolate cysts'. Ovarian endometriosis is frequently associated with dense adhesions, the ovaries being bound down to the broad ligament or bowel (Muir's textbook of pathology).

Microscopy

The chocolate-like appearance of the cyst fluid that gives an endometrioma its typical ground glass echogenicity is produced by endometrial shedding associated with cyst wall exudation, congested wall vessels and inflammation around intracystic endometrial foci (Brosens and Brosens 2000; Brosens and Puttemans 1994). Initially there is no real cyst wall, and the endometrioma is delineated by a very thin layer of endometriotic tissue. Later on the cyst wall becomes thickened and irregular due to fibrosis, acute and chronic inflammation, oedema of the cyst wall, necrosis and in some exceptional cases even decidualisation. Decidualisation during pregnancy

can stimulate the growth of solid tissue and increase the vascularisation making the differential diagnosis with ovarian cancer extremely difficult (Kawaguchi *et al.*, 2008).

Methods

The patients included in this study are all 3511 patients with validated data in the International Ovarian Tumour Analysis (IOTA) database (Timmerman *et al.*, 2000; 2005; Van Holsbeke *et al.*, 2009). The IOTA studies (IOTA phase 1 (Timmerman *et al.*, 2005), IOTA phase 1b (Van Holsbeke *et al.*, 2009), and IOTA phase 2 are large multicentre studies that prospectively collected patients with an adnexal mass. The patients were recruited in 21 different ultrasound centres in nine countries. They were all scanned transvaginally by an expert sonologist following a strict research protocol (Timmerman *et al.*, 2000). In addition to collecting information on more than 40 ultrasound variables and a few clinical variables, at the end of the ultrasound examination the sonologist classified the adnexal mass as benign or malignant using pattern recognition (subjective evaluation of ultrasound findings). Moreover, he/she reported the level of diagnostic confidence with which the prediction of benignity/malignancy was made and suggested a specific histological diagnosis. During the IOTA phase 1 study, the ultrasound examiner could suggest any diagnosis, but during IOTA phase 1b and 2 the examiner had to choose a specific histological diagnosis from a predefined list of 15 diagnoses (endometrioma, teratoma, (serous or mucinous) cystadenoma, simple cyst/para-ovarian cyst, functional cyst, hydro/pyosalpinx, peritoneal pseudocyst, abscess, fibro(thecoma), rare benign tumour, (serous or mucinous) borderline tumour, ovarian cancer, rare malignant tumour, metastatic ovarian cancer or not possible). Whenever the ultrasound examiner suggested more than one presumed diagnosis or said it was impossible to suggest a diagnosis, the suggested diagnosis was classified as inconclusive. A presumed diagnosis of "adnexal cyst", "complex cyst" or "benign ovarian cyst" was also regarded as inconclusive because this was not specific enough for the analysis of this study.

The gold standard was the histological diagnosis of the surgically removed adnexal mass. Only patients who had the adnexal mass surgically removed within 120 days after the ultrasound examination were included. More information on the IOTA studies and the ultrasound protocol can be found in published IOTA studies (Timmerman *et al.*, 2000, 2005; Van Holsbeke *et al.* 2009).

Sensitivity and specificity for pattern recognition to discriminate endometriomas from other adnexal

pathology was calculated, together with 95% confidence intervals based on Wilson's score interval method (Newcombe 1998). The true histologies of the false positive cases are reported (i.e. tumors wrongly characterised as endometriomas), as well as the presumed diagnoses of false negatives (i.e. endometriomas missed by pattern recognition).

Descriptive statistics for the ultrasound variables, some demographic variables and the serum CA-125 level were computed for true positives (i.e. endometriomas correctly presumed to be an endometrioma), false positives (benign and malignant), false negatives, and true negatives (i.e. tumours correctly presumed not to be endometriomas).

Results

During the IOTA phase 1, 1b and 2, a total of 3511 patients with an adnexal mass were prospectively included in 21 ultrasound centres from 9 countries. Of these, 2560 masses were benign (73%) and 951 malignant (27%). The dataset included 713 (20%) endometriomas (Table 1). An ultrasound diagnosis of endometrioma was made in 652 cases

of which 577 (88.5%) proved to be an endometrioma on final histology. Thus, pattern recognition distinguished endometriomas from other types of adnexal masses with a sensitivity of 80.9% (95% CI 77.9-83.6) (577/713) and a specificity of 97.3% (95% CI 96.7-97.9) (2723/2798).

Of the 652 presumed endometriomas, 75 (12%) proved to be something else on final histology. Sixty-six of these 75 false positive cases were benign, the most frequent histological types being functional cysts and cystadenomas (Table 2) (Fig. 1 and 2). However, in nine cases the presumed endometrioma turned out to be a malignancy (five borderline tumours, three endometrioid adenocarcinomas, and one case presumed to be an adnexal mass proved to be a uterine clear cell adenocarcinoma) (Table 2) (Fig. 3 and 4).

Nineteen percent of the endometriomas (136/713) were missed by pattern recognition. The specific histologies that were most often suggested in these cases were functional cysts and cystadenomas (Table 2).

Clinical and ultrasound features of true positives, false positives, false negatives and true negatives with regard to endometrioma using pattern recognition are presented in Table 3 and 4.

The true positive cases were most often unilocular (72.4% vs. 53% false positives benign and 33.3% false positives malignant, 33.1% false negatives, 35.8% true negatives benign, and 1.0% true negatives malignant. Ground glass echogenicity was seen in 84.2% of the true positive cases vs. in 60.6% of false positives benign cases, and in 25.0% of the false negatives, in 1.6% of the benign true negatives and in 5.4% of the malignant true negatives. However, all of the false positive malignant cases (n = 9) had ground glass echogenicity. Papillary projections were as common in the true positive endometriomas as in the false positive benign cases (7.8% and 7.6%) but less common than in all the other categories (11.1% in false positive malignant cases, 20.6% in the false negative cases, 16.8% in the true negative benign cases, and 40.1% in true negative malignant cases). Flow inside the papillary projections was rare in the true positive cases of endometrioma (1.6% vs. 3% - 11.1% - 6.6% - 4.2% - 30.4%). Within the groups of masses with papillary projections the true positive endometriomas most often contained only one papillation instead of several papillations (73.3% vs. 60.0% - 0% - 64.2% - 61.5% - 29.1%). The patients in the group of true positives were the youngest (median age 33 years vs. 39-50-40-46-56 years) and the least often postmenopausal (1.9% vs. 15.1% - 55.6% - 14% - 40% - 65.9%). When compared to the other groups, the sonologists were most often convinced about the benign character of

Fig. 1. — Unilocular cyst with ground glass echogenicity in a 39-year-old patient with a serum CA-125 level of 250 kU/l that was presumed to be an endometrioma but proved to be a functional cyst on final histology.

Fig. 2. — Unilocular cyst with ground glass echogenicity in a 64-year-old patient that was presumed to be an endometrioma but proved to be a mucinous cystadenoma on final histology.

the mass in the group of true positives (82.5% vs. 59.0% false positive benign, 11.1% false positive malignant, 50.7% false negative, 59.9% true negative benign).

The median serum CA 125 level was often above the suggested cut-off of 30 kU/ml to indicate malignancy in the group of the malignant true negatives (median 174 kU/l, (range 2-38161)) but also in the group of the true positives (46 kU/l, (range 4-3500)) and false negatives (38 kU/l, (range 2-9556)) (Table 4).

In the group of *false positive malignant cases* (n = 9), six cases were unilocular (n = 3) or multilocular (n = 3) and all had ground glass echogenicity. Only one case presented with papillary projections. The surface of the papillary projection was irregular and colour Doppler examination demonstrated flow inside the papillation. Most of these patients (5/9, 56%) were postmenopausal with a median age of 50 years. In one of the nine cases the sonologist was convinced that the mass was benign, in six cases the sonologist assumed it was probably benign and in two cases he or she was completely uncertain about the benign or malignant character. The serum CA 125 level was available for eight of the nine patients with a median CA 125 level of 24 kU/l.

Fig. 3. — Multilocular-solid mass with ground glass echogenicity of the cyst fluid and with a largest diameter of 108 mm in a 33-year-old patient that proved to be a mucinous borderline tumor of the endocervical type.

Fig. 4. — Multilocular cyst with two locules, ground glass echogenicity of the cyst fluid and a largest diameter of 22 mm in a 75-year-old patient undergoing the ultrasound examination for preoperative staging of endometrial cancer. The adnexal cyst proved to be a serous borderline tumor.

The group of *the false negative cases or “missed” endometriomas* (136/713, 19%) presented more often with atypical endometrioma features than the group of the true positives with only 9% (12/136) unilocular cysts with ground glass echogenicity. Twenty six % were multilocular-solid or solid compared to only 9% of the true positives. Only 25% had ground glass echogenicity of the cyst fluid compared to 84% of the true positives. The sonologists were also less confident about the benign character of the mass and in 18 cases (13%) even suspected a malignancy (Table 3) (Fig. 5).

Discussion

As far as we know the present study is the largest study examining not only the performance of pattern recognition to discriminate endometriomas from other types of adnexal masses but also examining the differences in morphology of the false positive and false negative cases, with the purpose of explaining the misclassifications. This study demonstrated that an expert sonologist can distinguish endometriomas from other masses, but that 1% of the masses presumed to be an endometrioma may be malignant.

In the past several authors reported that the ultrasound morphology of endometriomas is so characteristic that pattern recognition has excellent sensitivity and specificity with regard to endometrioma (Guerriero *et al.*, 1995, 1996, 1997; Mais *et al.*, 1993 (2), Patel *et al.*, 1999; Van Holsbeke *et al.*, 2009; Jermy *et al.*, 2001; Sampson 1921, Asch and Levine 2007; Alcazar *et al.*, 1997). In unpublished work (Van Holsbeke *et al.*, 2009) we have demonstrated that the diagnostic performance of pattern

recognition to discriminate between images of endometriomas and images of other types of adnexal masses is highly influenced by the level of ultrasound experience. The sensitivity and specificity of expert sonologists was very good (88% and 99%, respectively). However, for senior trainees in gynaecology, the sensitivity was only 56 and 69% and specificity 93 and 94%, and for junior trainees in gynaecology the sensitivity ranged between 6 and 69% and specificity between 91% and 97% (Van Holsbeke *et al.*, 2009). In this study the expert sonologists achieved a sensitivity of 81% and a

Certainly malignant							3	(2.2%)	16	(0.9%)	526	(55.8%)

*; concerns only those masses with a papillary projection (true positives: n = 45; false negatives: n = 28; false positives benign: n = 47; false positives malignant: n = ; true negatives benign: n = 299.

Table 4. — Description of demographic, clinical variables and serum CA 125.

Clinical or demographic variable	True positives, (n = 577)		False positives, benign (n = 66)		False positives, malignant (n = 9)		False negatives (n = 136)		True negatives, benign (n = 1781)		True negatives, malignant (n = 942)	
	n, (%)	(range)	n, (%)	(range)	n, (%)	(range)	n, (%)	(range)	n, (%)	(range)	n, (%)	(range)
Age, median (years, range)	33	(19-76)	39	(16-74)	50	(32-75)	40	(12-63)	46	(9-90)	56	(15-94)
Postmenopausal	11	(1.9%)	10	(15.1%)	5	(55.6%)	19	(14.0%)	711	(40.0%)	621	(65.9%)
Personal history of ovarian cancer	1	(0.2%)	3	(5%)	1	(11.1%)	2	(1.4%)	14	(0.8%)	33	(3.5%)
Pain during the ultrasound examination	216	(37.4%)	20	(30.3%)	1	(11.1%)	37	(27.2%)	330	(18.5%)	15	(15.4%)
Median CA 125# (kU/l)	46	(4-3500)	22	(2-800)	24	(11-78)	38	(2-9556)	15	(1-40140)	174	(2-38161)

#: concerns only those masses for which the serum CA 125 level was available (true positives: n = 364, false positives benign: n = 47, false positives malignant: n = 8, false negatives: n = 92, true negatives benign: n = 1293, true negatives malignant: n = 854).

specificity of 97% to discriminate endometriomas from other adnexal pathology. This is in line with previous studies that have evaluated the performance of pattern recognition in the diagnosis of endometriomas (sensitivity varying between 81 and 86% and specificity between 89 and 97% (Valentin 2004; Guerriero *et al.*, 1996, 1997; Mais *et al.*, 1993 (2); Jermy *et al.*, 2001; Guerriero *et al.*, 1995; Sampson 1921; Asch and Levine 2007; Alcazar *et al.*, 1997). The first prospective study that evaluated the ability of transvaginal ultrasound to discriminate endometriomas from other types of adnexal masses was performed by Guerriero *et al.* on a dataset of 93 adnexal masses that included 24 endometriomas. Pattern recognition gave a sensitivity of 83% and a specificity of 89% (Guerriero *et al.*, 1995). The false positive cases in their study had the same ultrasound characteristics as the true positive cases which is in contrast to our study where the endometriomas that were missed and the false positive cases had different ultrasound morphology. False negative cases or endometriomas missed by pattern recognition were most commonly thought to be cystadenomas, functional cysts, hydrosalpinges and abscesses or even ovarian cancer when using pattern recognition. We found that false positive cases occurred most commonly in functional cysts and cystadenomas. It is not surprising that these types of histologies were misclassified as endometriomas because the echogenicity of the cyst content of these masses (blood, pus or mucus) may appear as ground glass. Among these false positive functional cysts and cystadenomas the rate of ground glass echogenicity was 52% (13/25) and 60% (12/20), respectively. This is less than what we found in another unpublished study that described the ultrasound characteristics of 713 endometriomas. In the study cited 73% (520/713) of the endometriomas had ground glass echogenicity of the cyst content (unpublished data, Van Holsbeke *et al.*, 2009) instead of only 6% (109/1847) of the benign non-endometrioma cases (Van Holsbeke *et al.*, 2009). The whole IOTA database contained 116 functional cysts, 690 cystadenomas and 42 abscesses of which only 15 (13%), 36 (5%) and 11 (26%) had ground glass echogenicity. Of these masses with ground glass echogenicity 10/15 (67%), 11/36 (31%) and 5/11 (45%) were classified as endometriomas when using pattern recognition, most probably because of the ground glass echogenicity.

Amongst the false positive cases there were also nine cases of ovarian cancer. It is a concern that among these false positive malignant cases only three demonstrated overt features suspicious for a malignancy. Contrary to most other studies our dataset included both pre- and postmenopausal patients. The prevalence of cancer in this group of

postmenopausal patients with a presumed diagnosis of an endometrioma was 19% (5/26) whereas in the premenopausal group it was 0.6% (4/626). It is clear from this that there are risks associated with making a presumed diagnosis of an endometrioma in postmenopausal women.

The personal history of an ovarian cancer should also be taken into account because the recurrence of a borderline tumour or invasive ovarian carcinoma can initially also present as a small mass with ground glass echogenicity due to the haemorrhagic or necrotic cyst content. This was the case in one of the nine malignant masses misclassified as endometrioma.

In a previous study we demonstrated the poor value of CA-125 in the preoperative assessment of an adnexal mass (Van Calster *et al.*, 2007). Also in this study we found no benefit of measuring the serum CA 125 level for correct classification of the masses. The median CA-125 level was lower in the false positive malignant masses (median 24kU/l) than in the true positive cases (median 46 kU/l).

We should also stress that within the IOTA studies the ultrasound examinations were performed by expert sonologists. This may have led to an overestimation of the diagnostic performance of pattern recognition. Moreover, only patients who were operated on within 4 months were included. This means that a significant number of endometriomas that had overt features of an endometrioma on ultrasound are likely not to have been included, because of long waiting lists for benign surgery in some centres or because of conservative management. If these “easy” cases would have been included, the prevalence of cancer within the group of masses presumed to be an endometrioma would have been smaller.

We can conclude that expert sonologists are able to discriminate between endometriomas and other types of adnexal masses in most cases. The number of misclassifications and especially misclassified cancers could be significantly reduced by taking great care when making a presumed diagnosis of an endometrioma whenever the mass does not demonstrate ground glass echogenicity or if it is found in a postmenopausal patient.
