Abstract

Background

The dorsal root ganglion (DRG) is a key structure in the mechanism of symptomatic radicular pain, weakness and change in sensation. DRG localization can assist in the decision making process of which areas require decompression, and type of procedure that should be performed to treat radicular symptoms. In this study we determine dimensions of lumbar foramina, DRG and its relationship to the neuroforamina through anatomic and magnetic resonance imaging (MRI) evaluation. Agreement between MRI and anatomic assessment of DRG location will be determined.

Methods

Sixteen embalmed cadavers, 10 females and 6 males, aged 68 to 106 years had an MRI of the thoracolumbar spine followed by dissection. Measurements made included foraminal height and width, DRG size and nerve root take off angle. The center of the DRG and its relationship to the foramina were measured and the probability of agreement between anatomic and MRI assessment were made.

Results

The greatest width of the DRG was 6.5mm bilaterally at L5 (range 3.2-6.5mm). The nerve root take off angle was largest at L5 on the left (range 50.5o-58.8o) and L4 on the right (range 50.5o-57.2o). The center of the DRG was found bilaterally in the medial zone of the foramen of L1-4 and lateral zone at L5. Foramina size increased from L1 to L5 in the ventral to dorsal and cephalad to caudal direction. Pedicle width increased from L1 to L5. The estimated overall probability of agreement between anatomic and MRI DRG location was 86.3% (95% confidence interval = 77.5% – 92.0%).

Conclusion

The percentage of agreement between MRI and anatomic evaluation of lumbar DRG location significantly exceeded our pre-defined threshold of 70% ($p = 0.0013$).

Clinical Relevance

Our results aid in surgical decision-making as true anatomic position can be directly correlated to what's seen on MRI.

Keywords: lumbar spine, dorsal root ganglia, MRI, lumbar foramina, cadaver
Volume 9 Article 3 doi: 10.14444/2003

Background

The dorsal root ganglion (DRG) is a key structure in the mechanism of symptomatic radicular pain, weakness and change in sensation.¹ The neuroforaminal and extraforaminal regions are two areas of increased risk for nerve and DRG entrapment by disc herniations or degenerative osteophytes as the nerve root exits the spinal canal. DRG localization can assist in the decision making process of which areas require decompression, and type of procedure that should be performed to treat radicular symptoms. With the advancement of minimally invasive procedures and their increased utilization in thoracolumbar and lumbar surgery precise knowledge of nerve anatomy and its spatial arrangements are particularly relevant.^{2,3} Such knowledge can be used to decrease the incidence of nerve root damage.

In an effort to further enhance our anatomic knowledge of DRG location and its anatomic relationships we carried out this study to determine the foraminal and DRG measurements and the location of the DRG in relationship to the neuroforamina. This was performed with anatomic and magnetic resonance imaging (MRI). We also assessed the agreement between MRI and anatomic assessment of DRG.

Materials and Methods

Sixteen embalmed cadavers, 10 females and 6 males, aged 68 to 106 years old (mean age 85.7) were included in the study. Prior to dissection, the thoracolumbar spine specimens were evaluated with MRI. The cadavers were then dissected and anatomical measurements were made. These measurements include foraminal height and width, DRG size and nerve root take off angle. The center of the DRG was determined based on the widest portion of the nerve root sleeve. The center of the DRG and its relationship to the foramina were measured. This was determined by the location of the center of the DRG in relation to intraspinal, neuroforaminal or extraforaminal region.⁴ The neuroforamina was bisected in a medial to lateral fashion to create medial and lateral regions (Figure 1).

Fig 1. DRG region. Zone 1 and 2: intraspinal; Zone 3: medial neuroforamina; Zone 4: lateral neuroforamina; Zone 5: extraforaminal space.

Statistical Methods

To estimate the probability of agreement between anatomical examination and MRI, we created a mixed-effects logistic regression model, with the intercept removed. The response variable, which is agreement, was defined by whether the exact same positions were identified by both diagnostic measures for a given side (right or left) within one of the five levels of the specimen's lumbar spine. We included "Spinal Level" as a fixed effect (treated as categorical) and included a random effect for each specimen and a random effect for "side" (right versus left) within each specimen. Due to a large amount of missing data for L1, we excluded L1 values from analysis. Thus, the results for this study are only valid for L2-L5. We estimated the percent agreement within each spinal level and computed 95% confidence intervals. To obtain an overall level of agreement, we took a weighted average of the coefficients for each category of the variable Level and transformed from the logit scale to probability. A 95% confidence interval for this predicted probability was then computed. We hypothesized the overall level of agreement would be significantly greater than 70%.

Results

There were 16 cadavers included in the analysis. For the MRI portion of the study, 10 cadavers were missing information for L1. One specimen was missing information for both right and left L2 and one specimen was missing information for the left side of L2. Missing information resulted from injury to the specimen. For all other spinal levels, complete information was available for each specimen.

The greatest width of the DRG was 6.5mm both on the left and right of L5 (range 3.2-6.5mm)(Figure 1). The nerve root take off angle was largest at L5 on the left (range 50.5°-58.8°) and L4 on the right (range 50.5°-57.2°). The center of the DRG was found bilaterally in the medial zone of the foramen of L1-4 and the lateral zone at L5. (Figure 2) The foramina increased in size from L1 to L5 in both the ventral to dorsal and cephalad to caudal (pedicle to pedicle) direction. Pedicle width (medial to lateral) increased in size from L1 to L5 (Table 1).

DRG Size (mm). Width is the width of DRG at the pin (maximal width of DRG). The nerve root angle is determined from $\sin(O)$ calculated by the right/diagonal lines relative to the width.

Table 1. Lumbar Spine Demographic.

DRG Size (mm)	Left					Right				
	L1	L2	L3	L4	L5	L1	L2	L3	L4	L5

Width: sem	0.3	0.3	0.2	0.3	0.4	0.2	0.3	0.2	0.4	0.4
Nerve Root Angle	Left					Right				
	L1	L2	L3	L4	L5	L1	L2	L3	L4	L5
Angle (rounded to nearest 10th)	50.5	52.2	55.2	57.4	58.8	50.5	52.2	55.2	57.2	56.3

Key: DRG Region zone 1 and 2: intraspinal; zone 3: medial neuroforamina; zone 4: lateral neuroforamina; zone 5: extraforaminal space. Intervertebral Foraminal Size. Anteriorposterior (AP): maximal distance from posterior body/disk to facet joint. Pedicle to pedicle (PP) distance: inferior border of upper to superior border of lower pedicle. SEM: standard error of the mean. Angle determined via $\sin(O) = \text{right}/\text{diagonal}$.

Table 2 displays raw percent agreement for each level, both as a raw percentage and adjusted values obtained from the logistic regression model. Recall that the L1 level was not included in the regression model. As Level increased from 2-5, the model-adjusted percent agreement increased from 77.4% (Level 2) to 94.4% (Level 5). After adjusting for Level and correlated responses within specimens and side within each specimen, the estimated overall probability of agreement was 86.3% (95% confidence interval = 77.5% – 92.0%). This percentage of overall agreement significantly exceeded our pre-defined threshold of 70% ($p = 0.0013$).

Table 2.

Level	Raw Values		Model-Adjusted Values
	Proportion Agree	% Agree	% Agree (95% Confidence Interval)
1	8/12	66.7	----
2	22/29	75.9	77.4 (58.0, 89.5)
3	25/32	78.1	79.4 (61.2, 90.4)
4	28/32	87.5	88.6 (71.9, 95.9)
5	30/32	93.8	94.4 (79.0, 98.7)

Discussion

Lumbar disc herniation and degenerative osteophytes are a major cause of acute and chronic radicular symptoms, due to dorsal root ganglia compression.⁵⁻⁷ Patient history, physical examination findings and advanced imaging (ie MRIs) are used in the diagnosis of spinal disorders. They can show DRG entrapment and the regional position, which can be helpful when choosing the appropriate surgical intervention. The location of the DRG can be divided into intraspinal, neuroforaminal and extraforaminal regions. We were able to quantify anatomic measurements of the DRG, foramina and their relationship. The location of the DRG determined from anatomical and MRI evaluation proved to share an overall probability of agreement of 86.3%. We found that the DRG is positioned more lateral from L1 through L5.

DRG location and symmetry may be altered by surrounding structures.⁸Hamanishi found 30 pairs among 221 pairs of lumbar DRG to be asymmetric on MRI. For example, asymmetry can be seen on MRI as a result of a herniated disc stretching the nerve root posteriorly changing the DRG location. Tissue hypertrophy, arthropathy, scoliosis and congenital conditions can be an etiologic cause as well. We found 2 of 68 pairs and 12 of 68 pairs of lumbar DRG to be asymmetric from anatomic and MRI evaluation, respectively.

Our study found a high percentage of L5 DRGs to be located in the neuroforaminal space. Kikuchi et al⁹ evaluated DRG location of the lower lumbar spine in a comparison study of 22 cadavers undergoing anatomic and radiographic assessment (with nerve root enhancement). He determined the anatomic location of L5 DRG to be 19.2% intraspinal, 72.8%, intraforaminal, and 8% extraforaminal compared to 38.9% intraspinal, 52.7% intraforaminal and 8.4% extraforaminal based on radiograph assessment ($p < 0.5$). The slight variation in findings from Kikuchi is twofold. Kikuchi et al. measures the DRG location based on the proximal end of the DRG. We determined the location based on the widest portion of DRG within the particular zone. Also, there is a slight variation in the fashion of zone designation.

A higher incidence of foraminal stenosis is found in the lower lumbar segments. Jenus and An determined the most common entrapped roots are L5 (75%), L4 (15), L3 (5%) and L2 (4%).^{10,11}Our data shows the L4 and L5 levels to contain the DRG in the neuroforamina. This is important when planning a surgical approach. For example, when the patient's symptoms are a result of pure foraminal stenosis an extraforaminal decompression using a paramedian Wiltse type approach with foraminotomy can be most appropriate.¹²

While the Wiltse paramedian approach is a common procedure for performing foraminal decompression, endoscopic transforaminal decompression has gained much popularity.¹³⁻¹⁵ Transforaminal approach provides access for foraminal decompression with less destabilization compared to a midline and Wiltse approach.¹⁶Endoscopic transforaminal decompression, while used during primary decompression, also has been utilized for revision lumbar surgery.¹⁷ Under endoscopic foramen visualization, stenosis can be seen as an absence of fat, vascular pulsation with scarred, fibrotic nerve roots in the axilla between the exiting and traversing nerves. This area is known as the hidden zone of McNab.^{17,18} Our study provides valuable anatomic knowledge as endoscopic transforaminal decompression utilizes a small window of visualization. Foraminal zones as described in this study can be accessed with a transforaminal approach from lateral to medial. Careful evaluation of pre-operative MRI findings will provide spatial relationships between the DRG and its surrounding structures. In addition to MRI, CT imaging with sagittal and coronal reconstruction can further aid in spatial assessment.

Pedicle width is noted to increase in size from L1 to L5 in our study. Kadioglu et al¹⁹ found the pedicle width to increase from L1 to L5 as well. They reported pedicle width to range from 4 to 14mm. As pedicle width increases from L1 to L5, the neuroforamina width will increase as well. Thus, it is more likely that the DRG will be found within the neuroforamina in the lower lumbar spine. Implication of this would include the need for a smaller versus larger foraminotomy to create space following DRG impingement.

Steroid injections are commonly performed for treatment of radiculopathy.²⁰⁻²²The location of administration may vary, however. DRG compression can be the etiology for symptoms. Hence, MRI verification of the DRG location can help with procedural planning. Also, MRI can be used for guidance imaging as well.²³With our results of a greater than 70% agreement the DRG location determined from MRI is similar to anatomic evaluation increases the likelihood medication infiltration will be at the appropriate location around the DRG.

Lumbar DRG motion is dynamic with slight positional change with activity. Smith et al²⁴ documented up to 5mm of linear displacement in unembalmed cadavers during straight leg raise (SLR) maneuver following laminectomy with facetectomy. They found movement to increase when hip flexion increased from 30° of flexion. During intraoperative assessment following lumbar discectomy, Kobayashi et al²⁵ found up to 4mm of root displacement. Grimes et al²⁶ described 4 distinct ligamentous bands connecting the root sleeve to the surrounding foraminal structures. These attachments are suggested to restrict distal displacement of the nerve roots. Thus, dissections performed by Smith and Kobayashi may in fact exaggerate movement. Gilbert et al²⁷ found the L4, L5 and S1 to move on average less than 1 mm during SLR when hip flexion was greater than 60° with intact foraminal ligaments in unembalmed cadavers. Thus, this little motion which can also relate to standing and sitting would likely result in the DRG remaining within the neuroforamen.

In this study we were able to describe the spatial arrangement of the dorsal root ganglia within the lumbar spine. In addition, we were able to quantify the foraminal dimensions and nerve root take off angles which both contribute to our understanding of the anatomical relationships of the lumbar spine.

While we were able to determine MRI and anatomic agreement, the study did face some limitations. The sample size was small and some levels were unable to be included in analysis secondary to poor anatomic and MRI visualization. Further evaluation could increase the power of this study. With changes in fat composition and lack of CSF in cadavers, there may be a slight change in the DRG location.

Conclusion

The percentage of overall agreement between MRI and anatomic evaluation of lumbar DRG location significantly exceeded our pre-defined threshold of 70% ($p = 0.0013$). Our results can aid in surgical decision-making as true anatomic position can be directly correlated to what is seen on MRI.
