#### Abstract

**Background**—The National Quality Forum has endorsed a 12 lymph node (LN) minimum as a surrogate measure of quality in colorectal cancer (CRC). The prognostic value of ultra-staging Hematoxylin and Eosin (H&E) negative LNs (N0) using pan-cytokeratin immunohistochemistry (pan-CK-IHC) is unknown.

Purpose—To assess the impact on survival of surgical quality and focused pathological analysis.

**Patients and Methods**—Between 2001 and 2007, 253 evaluable patients with resectable CRC were enrolled. Multiple sectioning and pan-CK-IHC was performed on N0 LNs (AJCC Stage II). Follow-up was performed at 6-month intervals with a 4-year disease free survival (DFS) primary end-point.

**Results**—There were 253 patients, 177 N0 and 76 N1/N2 patients, staged conventionally. Thirtysix (20%) N0 patients were upstaged using ultra-staging [N0 $\rightarrow$ N0i+ (n=27) and N0 $\rightarrow$ N1mi (n=9)]. At a mean follow up of 3.4±1.6 years, 38 (15%) have recurred. Only 3% (3/108) of patients with 12 LNs, negative by H&E and pan-CK-IHC (N0i-), compared to 18% (6/33) with <12 LNs/N0i- (6/33; p=0.0015) have recurred. Four-year DFS differed significantly according to surgical quality (<12 vs. 12 LNs) amongst Stage II patients only (DFS, <12 vs. 12 LNs: Stage I, 90.5% vs. 97.7%, p=0.22; Stage II, 67.5% vs. 94.7%, p=0.0036; Stage III, 61% vs. 61%, p=0.61).

**Conclusion**—This represents the first prospective report demonstrating that both surgical quality and nodal ultra-staging impacts survival in Stage II CRC. Patients with Stage II CRC having 12 LNs negative for micro-metastases (N0i-) are likely cured by surgery alone. Both surgical and pathological quality measures are imperative in early CRC in order to improve patient selection for adjuvant chemotherapy.

colon cancer; staging; surgical quality; micrometastasis

#### Introduction

Colorectal cancer (CRC) is the third most frequently diagnosed cancer and the second leading cause of cancer mortality in the United States <sup>1</sup>. Within the AJCC cancer staging system regional nodal tumor dissemination in the absence of distant metastasis differentiates Stage III from Stage I/II disease <sup>2</sup>. In fact, the staging of CRC as well as the decision to utilize adjuvant systemic therapy to a great extent relies on the tumor status of the regional lymph nodes (LNs) <sup>3</sup>. In patients with non-metastatic disease, regional nodal dissemination is a principal determinant of cancer outcomes. Importantly, the number of mesenteric nodes removed surgically as well as the number of nodes assessed pathologically governs not only accuracy of tumor staging, but also overall survival <sup>4</sup>-<sup>6</sup>.

The unacceptably high rate of disease recurrence in patients undergoing surgical resection of apparently LN-negative (N0) disease is attributable in part to incomplete resection of tumorbearing regional LNs, possible stage migration (the Will Rogers Phenomenon) and under-

treatment (failing to treat under-staged patients with systemic therapy) <sup>2,5,7</sup>. There is wide variation in number of LNs retrieved surgically from patients with CRC. In a large population-based analysis in the United States we found that the median number of mesenteric LNs resected at time of colectomy in patients with colon cancer (CC) was nine and the mode, zero<sup>4</sup>. Consensus-driven quality improvement initiatives in cancer care have emerged as a result of this and other studies pointing to unacceptably low nodal yield from surgical specimens. These multi-disciplinary, evidence-based practice management and quality improvement efforts involve the National Cancer Institute and Veteran Health Affairs (Cancer Care Outcomes Research and Surveillance, CanCORS), the American Society of Clinical Oncology (ASCO), RAND/Harvard and Commission on Cancer (CoC) of the American College of Surgeons (ACS), National Initiative on Cancer Care Quality (NICCQ), National Quality Forum (NQF), and, National Comprehensive Cancer Network (NCCN). The ACS CoC submitted consensus standards for the diagnosis and treatment of CRC to the NQF, which through collaboration with ASCO and NCCN developed two agreed upon national consensus quality standards for CRC: (1) 12 lymph nodes removed surgically and examined pathologically for resected colon cancer; and, (2) adjuvant systemic therapy considered or administered within 120 days of diagnosis for patients under age 80 with AJCC Stage III disease 8-11.

Under-staging may also reflect tumor biology as well as the inherent limitations of conventional pathological nodal assessment in detecting low volume disease: <1% of any given LN is assessed morphologically by standard hematoxylin-eosin (H&E) microscopy resulting in sampling error <sup>4</sup>,<sup>14</sup>,<sup>15</sup>. These undetected micrometastases (MM) may account for the high (20-30%) rate of disease recurrence after surgical resection of Stage II colon cancer <sup>12</sup>,<sup>13</sup>. The clinical relevance of MM detected by pancytokeratin immunohistochemistry (pan-CK-IHC) found to be negative by H&E staining in patients with colon cancer <sup>16</sup> have not however been uniformly accepted. Our group has demonstrated the utility of ultra-staging with nodal step sections and pan-CK-IHC for the detection of occult nodal disease, and has underscored the potential prognostic impact of MM in our ongoing efforts to not only standardize the surgical and pathological evaluation, but also improve patient selection for adjuvant therapy of Stage II colon cancer <sup>12</sup>,<sup>13</sup>,<sup>17</sup>,<sup>18</sup>. The present analysis of two international prospective trials was undertaken to assess the impact of surgical quality and nodal ultra-staging on long-term disease-free survival (DFS) in early CRC.

#### **Methods**

#### Specific aims

We aimed to assess the impact on DFS of: (1) surgical quality (<12 versus 12 or more nodes resected surgically and assessed pathologically); and, (2) focused pathological assessment (step section and pan-CK-IHC detected presence or absence of MM disease amongst AJCC Stage II: N0i- versus N0i+) in enrolled study subjects with non-metastatic (AJCC Stage I-III) adenocarcinoma of the colon and rectum. A well characterized cohort with long-term follow up derived from two prospective observational trials of targeted nodal assessment in CRC was used for analysis. This study represents the work of a clinical research consortium

including the United States Military Cancer Institute, Cancer Centers within the United States, Europe and Israel.

#### Primary endpoint

The primary outcome variable in this study was 4-year DFS. DFS was defined as time from study enrollment to the first documentation of disease recurrence or death.

#### Study population

Two hundred fifty-three patients provided written informed consent and were enrolled over a 6-year study period in two prospective multi-center clinical trials of LN ultra-staging in CRC <sup>12</sup>, <sup>17</sup>. Eligibility criteria have been previously described <sup>12</sup>, <sup>17</sup>. In brief, study subjects were adults (18 years of age or older) with potentially curable primary non-metastatic colon (n=217) or rectal (n=36) carcinoma detected by endoscopy. Patients were considered noneligible if they were found to have metastatic disease intra-operatively or failed to meet the major eligibility criteria. Patients with CRC were followed at six-month intervals for four years post-operatively. Colonoscopy was obtained 1 and 4 years after surgery and a chest radiograph and computed tomography scan (CT) of the abdomen and pelvis annually. An analysis of pooled data was then performed. Institutional Review Board approval for this study was provided by University of California Los Angeles, California (#09-09-088-01) and Hadassah Medical Organization, Jerusalem (#16-28-03-03).

#### Surgical technique and pathological nodal assessment

Surgeons enrolling patients in these trials were experienced surgical oncologists and colorectal surgeons that have demonstrated technical competence and perform at least twenty colorectal cancer operations a year. An oncologic resection was performed to include all regional mesenteric lymph nodes. Standard histopathological examination was performed on the resected colon and/or rectal specimen as well as the surrounding LNs. Ultra-staging of the H&E negative LNs by pan-CK-IHC was performed as previously described <sup>12</sup>,<sup>17</sup>.

Serial step sectioning at 40-200 micrometer intervals was conducted on formalin-fixedparaffin embedded LNs. Four 4-micrometer sections were stained with H&E (1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup>, and 4<sup>th</sup> sections) and two (2<sup>nd</sup> and 4<sup>th</sup> sections) were evaluated with pan-CK-IHC. The avidin-biotin-peroxidase complex method was used for the IHC according to a standardized protocol (Pan-keratin AE1/AE3, CAM 5.2, 35bH11; Ventana Medical Systems, Tucson, AZ) <sup>12</sup>, <sup>17</sup>, <sup>19</sup>. In order for isolated tumor cells (ITCs) or cell clusters (CCs) within the LNs evaluated with pan-CK-IHC to be considered positive, two criteria had to be met: (1) cells had to stain strongly positive; and, (2) cells had to demonstrate anatomical and cytological features of carcinoma. A pan-CK-IHC-positive node was defined as a LN containing single cells or cell clusters (largest cluster 0.2mm) demonstrating morphological features consistent with CRC apparent on evaluation of H&E and/or pan-CK-IHC stained sections of the node. Tumor deposits within LNs were classified and staged according to the revised guidelines set by the American Joint Commission on Cancer (AJCC, 2002 6th Edition) and International Union Against Cancer (UICC) <sup>20</sup>, <sup>21</sup>. The largest LN cluster of cohesive aggregates of carcinoma cells was measured. Metastases less than 2 mm and greater than 0.2 mm (>0.2 to <2 mm) were considered MM (N1mi); isolated tumor cells or cell clusters up to 0.2 mm ( 0.2 mm) were usually detected by IHC (Figure 1) and classified (N0i+). Rare single cells staining positive with IHC that lacked cytological characteristics of malignancy were considered tumor-negative (N0i-).

#### **Statistical Analysis**

All data were reviewed and analyzed by the Department of Biostatistics at UCLA (DAE) and the Department of Clinical Investigation, Division of Biostatistics, Walter Reed Army Medical Center (RH). Summary statistics were obtained using established methods. The categorical variables were compared between groups using Fisher exact test or  $\chi 2$  test as appropriate. Continuous data are presented as means and standard deviations (mean  $\pm$  SD) and were compared using the two-sample t-test. If assumptions for normality were not satisfied (determined by the Shapiro-Wilk test) then data were summarized using the median and range and groups were compared using the Wilcoxon rank sum test. All tumor staging was conducted according to the American Joint Commission on Cancer (AJCC TNM) Staging (2002, 6th edition) criteria. The mean, median, and mode of the number of lymph nodes examined were determined. Based on the national guidelines, analysis was stratified by those with 12 or more, and those with fewer than 12 nodes resected surgically and examined pathologically, and in conventionally staged N0 (AJCC Stage I/II patients) stratified according to IHC results: N0(i-) [H&E(-)/pan-CK-IHC (-)] versus N0(i+) [H&E(-)/pan-CK-IHC (+)].

Demographic and clinical factors associated with surgical resection of 12 or more nodes were examined in a multivariate model using logistic regression. Variables which had a p value 0.20 in the univariate analysis were entered into the model. The final model included those variables which were significant at the p<0.05 level and are presented with odds ratios together with 95% confidence intervals.

The primary outcome variable in this study was DFS, which was defined as time from study enrollment to the first documentation of disease recurrence or death as a result of any cause, whichever came first. DFS analysis was undertaken using the Kaplan-Meier method. Survival differences were analyzed utilizing the Log-rank test. A Cox proportional hazards model was used for multivariate analysis. Factors potentially significant (p<0.05) on univariate analysis were entered into the multivariate model. The models were obtained by starting with all significant factors (univariate p<0.05) in the model and removing, stepwise, factors that were not significant in the multivariate analysis. Hence, a hierarchical forward stepwise methodology was used to screen clinical/pathological variables for model inclusion. Separate models were created for those with 12, and those with <12 LNs. We included variables at a significance level of p<0.05. Statistical analysis was performed using SPSS v17.0 (SPSS, Inc, Chicago IL). Significance levels were set at p<0.05. All tests were two sided.

#### Results

#### **Clinical and Pathological Characteristics**

Of the 253 evaluable patients, 135 were female (53%) and 118 male (47%), with a median age of 71 years. Baseline demographic and clinical characteristics of the entire study population are shown in Table 1. Mean body mass index for the study population was  $25.7 \pm 4.4 \text{ kg/m}^2$  and over half of the patients were either overweight (38%; BMI 25.0-29.9 kg/m<sup>2</sup>) or obese (15%; BMI 30 kg/m<sup>2</sup>). Most tumors were of colonic origin. Primary tumors were located in the colon in 217 (86%) patients, in the rectum in 36 (14%) patients.

The majority of patients (93%) underwent open segmental resection of the colon. Types of resection performed included: right colectomy (n=114; 45%), sigmoid colectomy (n=50; 20%), low anterior resection (n=37; 14%), total colectomy (n=25; 10%), left colectomy (n=22; 9%), transverse colectomy (n=3; 1%), total proctocolectomy (n=1; <1%), and APR (1; <1%).

Over 70% of tumors invaded through the muscularis propria and into the subserosa, pericolonic tissues or adjacent organs (AJCC T3 or T4). Median primary tumor size was 3.6 cm and over 80% of tumors were of intermediate (67%) or high (16%) histological grade. Microscopically apparent lymphovascular invasion was identified in 11% of primary tumors.

The mean number of LNs staged was  $20 \pm 12$ . Over 80% (205/253) of patients had 12 or more LNs resected surgically and evaluated pathologically, and a third (76/253; 30%) were node positive [AJCC N1 (n=50) or N2 (n=26); Figure 2] by conventional histopathology (H&E). Mean number of resected and mean number of positive nodes identified according to surgical quality indicator, < 12 versus 12 nodes were as follows: resected, 8.0 (< 12 nodes) versus 22.0 (12 nodes); and, mean # positive nodes, 0.6 (< 12 nodes) versus 2.0 (12 nodes). By multivariate logistic regression analysis (Table 2) only primary tumor size (p=0.01) and tumor location (colon vs. rectum) (p=0.013) were associated with increased LN retrieval (12 LNs).

Of the 177 H&E node negative (AJCC N0 by conventional staging) patients, 27 (15%) were found to have IHC-positive ITCs in ultra-staged nodes (N0 $\rightarrow$ N0i+) Figure 2. Most (21/27; 78%) of these patients had T3 tumors. A majority of these upstaged patients did not have lymphovascular invasion (23/27; 85%) identified in the primary tumor.

Of the 177 H&E node negative (AJCC N0 by conventional staging) patients, 9 (5%) were found to have micrometastases (MM) by ultrastaging (N0 $\rightarrow$ N1mi). Hence, nine (11%) of the overall 85 node positive patients (AJCC N1 or N2) were upstaged by nodal step sectioning and pan-CK-IHC from H&E N0 to nodal MM (N0 $\rightarrow$ N1mi) (Figure 2). Most (7/9; 78%) of these patients had T3 or T4 tumors and none had lymphovascular invasion apparent on microscopic assessment of the primary tumor. The distribution of nodal disease volume is shown in Table 1, where ITCs or MM were identified in 14% (36/253) of patients with nodal ultra-staging. Thus, 20% (36/177) overall upstaging [N0 $\rightarrow$ Ni+ (n=27) and N0 $\rightarrow$ N1mi (n=9); Figure 2] was conferred by detailed nodal assessment (step section  $\rightarrow$  H&E and pan-CK-IHC).

#### Follow up and Disease Free Survival

At a mean follow-up of 38.4 months (median 38 months), 38 of the 253 (15%) evaluable patients have experienced disease recurrence (8 local, 30 distant). Disease recurrence according to AJCC Stage is shown in Table 3 along with stage-specific adjuvant systemic therapy indicated. Four-year stage-specific DFS according to number of nodes resected surgically and examined pathologically is shown in Table 4. A statistically significant difference in 4-year DFS was found in all AJCC Stage II patients in relation to nodal yield (< 12 vs. 12 nodes: 68% vs. 95% DFS; p=0.0036). Only 3% (3/108) of N0 patients with 12 LNs, negative by both H&E and pan-CK-IHC (N0i-), compared to 18% (6/33) with <12 LNs, negative by both H&E and pan-CK-IHC (N0i-), have developed disease recurrence (p=0.0015) (Table 5).

Disease recurrence varied significantly according to nodal disease volume: N0i-: 6%(9/141); N0i+: 7%(2/27); N1mi: 22%(2/9); N1/2: 33%(25/76); p<0.001 (Table 6; Figure 3). Hence, the finding of ITCs and cell clusters ( 0.2 mm) in LNs by nodal ultra-staging with pan-CK-IHC in otherwise conventionally staged N0 patients did not have an impact on DFS: disease recurrence, N0i- vs. N0i+: 9/141(6%) vs. 2/27(7%); p=0.92. However, 26% of patients with N0i+ received adjuvant chemotherapy vs. 11% of N0i- who did not (p = 0.054). In the N1/N2 group (Stage III), most (92%) patients were treated with adjuvant chemotherapy (Table 3). In the rectal cancer group 17/36(47%) were treated with neoadjuvant radiation therapy.

When recurrence according to nodal disease volume was assessed on a site-specific (colon versus rectum) basis, the same finding of disease recurrence varying significantly with nodal disease volume was demonstrated in the colon (p<0.001), but not the rectal cancer population, although the latter subset was decidedly small (Table 6). Disease recurrence between patients found to be node negative by step section and pan-CK IHC (N0i-) was 6% (9/141) compared to 11% for upstaged N0 patients (N0 $\rightarrow$ N0i+ and N0 $\rightarrow$ N1mi; 4/36). Hence, there was no significant difference between patients upstaged by nodal ultra-staging, N0i+ and N1mi, and those that remained node negative (N0i-) following detailed pathological assessment (p=0.41). Disease recurrence according to anatomic site (colon and rectum, colon only, rectum only), nodal disease burden [N0i-: H&E(-)/pan-CK-IHC(-) vs. N0i+: H&E(-)/pan-CK-IHC (+)] and surgical quality indicator (< 12 vs. 12 nodes) amongst patients with AJCC N0 stage disease is shown in Table 5. A significant difference in rate of disease recurrence was identified amongst patients with negative nodal ultrastaging [AJCC N0i-: H&E (-) / pan-CK-IHC (-)] according to surgical quality or nodal yield for the entire group (Figure 4) as well as the colon-only study population. By multivariate analysis LN number ( 12/<12) and LN status interaction effect (N0i-: H&E(-) / pan-CK-IHC(-) vs. other groups) were independent significant factors (p=0.01), Table 7.

#### Discussion

This study addresses an imperative in colon cancer - that of improving the accuracy of nodal pathological assessment, recognizing that this assessment is critical to disease staging and treatment planning. The present analysis of two international prospective trials was undertaken to assess the impact of surgical quality (< 12 vs. 12 nodes) and nodal ultrastaging (step section  $\rightarrow$  H&E and pan-CK-IHC) on DFS in early CRC. DFS differed significantly according to surgical quality in this study amongst AJCC Stage II patients, emphasizing that both surgical and pathological quality measures are critical in early CRC in order to facilitate judicious adjuvant treatment decisions.

The incidence of node-negative (N0) CRC is increasing in the United States because of improved public awareness and greater access to screening colonoscopy, which enables earlier detection of disease. Despite this, up to one third of patients recur, possibly due to inadequate lymphadenectomy or inaccurate standard pathological staging techniques leading to overlooked nodal metastases. This has resulted in considerable debate about the utility of adjuvant chemotherapy in Stage II colon cancer. In a recent review of 37 randomized trials and 11 meta-analyses in over 20,000 patients <sup>22</sup> with AJCC Stage II (N0) colon cancer, there was a 5-10% improvement in DFS with adjuvant chemotherapy, but this did not translate into a statistically significant improvement in overall survival. Within these trials however, there were certain subsets of patients with survival similar to Stage III (node-positive, N1/N2) colon cancer. These largely represented patients with incomplete surgical resection and/or pathological assessment (< 12 nodes). This is further supported by pooled analyses of data from randomized trials <sup>23</sup>, <sup>24</sup> which demonstrated a strong correlation between survival and number of LNs examined independent of other known prognostic factors. In a large Intergroup Trial analysis (INT 0089), an improvement in 5-year survival from 73% to 87% was reported in Stage II colon cancer when the number of LNs recovered increased from <10 to  $>20,^{6}$  a larger impact than any adjuvant treatment has attained to date.

Both the AJCC and the UICC recommend the examination of at least 12 LNs per specimen<sup>20</sup>,<sup>21</sup> and this has been endorsed nationally as a benchmark for hospital-based performance<sup>25</sup>,<sup>26</sup>. The ACS CoC endorses the NQF consensus standard for CRC: surgical retrieval and pathological evaluation of 12 LNs. This does not however address inconsistencies in pathological evaluation, LN sampling errors in the face of small nodal disease deposits, and the significant limitations of conventional H&E to detect occult nodal metastases.

This analysis of two prospective trials was performed to evaluate whether surgical quality (12 LNs) and focused pathological analysis using multiple nodal sectioning and pan-CK-IHC improves the detection of occult metastases and impacts 4-year DFS. Overall, 36 of 177 patients (20%) were found to have nodal MM (N0 $\rightarrow$ N1mi, n=9) and ITCs (N0 $\rightarrow$ N0i+, n=27), which were not detected by conventional (H&E) staging methods (Figure 2). Nine of 85 (11%) Stage III patients were upstaged with nodal ultra-staging from N0 to N1mi, potentially impacting adjuvant therapy decisions. The 4-year DFS was significantly higher (95%) in Stage II patients with 12 nodes compared with <12 nodes (68%). Only 3% of N0 patients with 12 LNs, negative by both H&E and pan-CK-IHC have recurred compared to

18% with <12 LNs and N0i. Nodal yield did not impact survival in Stage III colon cancer in this study.

Colon cancer recurrence varied significantly according to nodal disease volume (Table 5, Figure 3), but the finding of ITCs and cell clusters (0.2 mm) alone detected by pan-CK-IHC (N0i+) did not impact recurrence; however, these patients were twice as likely to receive adjuvant systemic therapy compared to N0i- patients. However, when surgical quality (12 LNs) was combined with pathological ultra-staging [step section  $\rightarrow$  H&E and pan-CK-IHC: H&E (-) / IHC(-): N0i-] there was a significant improvement in DFS amongst node negative (N0) patients (Table 6, Figure 4). These data suggest that patients who meet the 12-node minimum benchmark, and are negative by both H&E and pan-CK-IHC step section assessment are likely cured by surgery alone (Table 7), and will not benefit from adjuvant chemotherapy; however the impact of ultrastaging on Stage III colon cancer is less apparent. This raises several important questions. Does the improvement in survival reflect Stage migration (i.e. the "Will Rogers" phenomenon), the response to adjuvant systemic therapy in those patients that are upstaged with nodal ultra-staging, the resection of micro-metastases (suggesting micro-metastases have prognostic value), better surgery alone or a combination thereof?

Stage migration suggests that the higher the number of nodes examined the greater the chance of finding positive LNs, thereby improving the selection of patients for adjuvant systemic chemotherapy. In a series of 35,787 cases of Stage II colon cancer from the National Cancer Data Base (NCDB), the 5-year survival for Stage II patients was 64% if only one or two LNs were examined versus 86% if more than 25 LNs were examined<sup>27</sup>. The NCDB investigators concluded that at least 13 lymph nodes should be retrieved and declared negative for an *accurate* diagnosis of Stage II disease to be attained. In our review of the Surveillance, Epidemiology, and End Results (SEER) database in more than 82,896 patients treated between 1988-2000, the 5-year survival in Stage II colon cancer was 78% when 15 nodes were evaluated compared with 70% for 8-14 nodes and 66% for 1-7 nodes (p < 0.001). For all colon cancer stages increased nodal sampling was associated with improved survival<sup>4</sup>. The resection of at least 15 lymph nodes was associated with significantly prolonged median overall survival by 11 months in patients with Stage I disease, by 54 months in Stage II, and by 21 months in Stage III disease. Interestingly, in our prospective trial LN number did not impact survival in Stage III colon cancer. This may reflect that the majority of patients received more effective oxaliplatin-based chemotherapy, which was not available during the data collection period of the SEER review, where adjuvant therapy was largely 5-Fluorouracil and Leucovorin, or it may reflect limited sample size on which the analysis was based.

The potential prognostic value of nodal MM detected by ultra-staging in N0 (by conventional H&E) colon cancer remains unresolved. In the current study ITCs detected by pan-CK-IHC failed to significantly impact 4-year DFS in patients with LNs otherwise staged negative by conventional pathological evaluation (H&E). This may be a consequence of modest sample size and associated lack of statistical power, or the influence of nodal MM alone (ITCs) on decisions regarding the administration of adjuvant chemotherapy. In this study, treating physicians were not blinded to the pathology reports and this likely reflects

the number of N0 patients with ITCs (N0i+) who subsequently received adjuvant chemotherapy. Even though no clear benefit of chemotherapy has been demonstrated in this setting, this group may be among those who derive benefit from adjuvant therapy.

Alternatively, tumor cells detected by IHC may not be as prognostically relevant as those detected by molecular assays including quantitative reverse transcriptase-polymerase chain reaction assay (qRT-PCR). The prognostic value of micrometastatic lymphatic disease was evaluated in a meta-analysis of all N0 colon cancer between 1991 and  $2002^{28}$  that reported overall survival. All studies identified MM after subjecting N0 LNs (by H&E) to greater pathological scrutiny. Molecular techniques using qRT-PCR upstaged 37% of patients from N0 to N0mol+ and were associated with an absolute survival difference at 3 years of 19%. Overall survival at 3 years was 78% for patients with molecularly detected MM N0mol+ and 97% for patients without molecularly detected MM [N0mol-; p<0.001]. Histological techniques including serial sectioning with IHC staining upstaged 32% of pN0 patients (N0 $\rightarrow$ N0i+). Although MM identified with IHC techniques appeared to adversely affect survival, the differences were not statistically significant, possibly due to variations in IHC techniques. These variations included differences in the nodal counts per specimen, nodal sections analyzed with IHC per specimen, volume of nodal analysis, the range of anticytokeratin antibodies used and the different definitions used to describe MM.

Changes in the AJCC 6<sup>th</sup> addition Cancer Staging Manual<sup>20</sup> and the identification of MM in the sentinel node(s) from patients with melanoma and breast cancer have provided standardized terminology that has decreased technical variations in pathological assessment among subsequent studies. Although the sentinel node concept has been effectively applied to CRC<sup>17</sup>,<sup>19</sup> it will largely remain investigational until the biological relevance of MM has been definitively established. Once this is established, targeted nodal assessment in CRC may ultimately prove to be a sensitive, expedient and cost-effective technique for the evaluation of nodal MM.

Primary tumor characteristics in addition to nodal evaluation are also an essential component in establishing a prognostic profile and predicting disease behavior. The presence of primary satellite tumor deposits has been associated with higher incidence of metastatic recurrence and therefore was recently incorporated into the revised AJCC 7<sup>th</sup> edition as N1c disease<sup>29</sup>. Intra-tumoral molecular profiling and specific gene signatures (18q loss of heterozygosity, DNA microsatellite instability, p27, KRAS mutation and thymidylate synthase) may prove to be associated with patient prognosis or response to therapy independent of nodal status<sup>30\_32</sup>. Although these factors may become part of a more comprehensive staging system, lymph node evaluation continues to be the most important prognostic factor, and clinical decision determinant in colon cancer. For this reason it is imperative for the surgeon to apply oncological principles to optimize nodal yield and for the pathologist to utilize techniques to improve the identification of smaller lymph nodes and nodal tumor deposits - micrometastases.

Continued emphasis must be placed on standardizing the pathological and surgical evaluation of patients with N0 CRC. Whether examining a larger number of LNs with ultrastaging techniques minimizes the false-negative results associated with standard H&E

assessment and improves staging and prognosis remains to be determined. This study represents the first prospective trial to confirm that the "12 lymph node benchmark" is an important prognostic factor in N0 colon cancer and that patients who meet this quality measure and have LNs negative for MM are likely cured by surgery alone. Our ongoing international prospective multicenter trial (2RO1CA090848) will establish a prognostic profile combining molecular signatures and nodal ultra-staging in Stage II colon cancer. Patients in this trial will not receive adjuvant chemotherapy which will allow us to further improve risk stratification and provide individualized clinical decision support.
