C. 20012, the Department of Medicine, University of Connecticut School of Medicine, Farmington, Connecticut 06032, and the Medical Service, Veterans Administration Hospital, Newington, Connecticut 06111

ABSTRACT Epinephrine infusion causes variable increases in the components of the Factor VIII (antihemophilic factor) complex in patients with von Willebrand's disease. The increase in antihemophilic factor procoagulant activity was greater than that of Factor VIII-related antigen and von Willebrand factor activity in two patients with von Willebrand's disease. Similar increases in the three individual factors were demonstrated in two other patients. A 4–10-fold increase in Factor VIII-related properties was identified in each of these individuals after infusion. One patient has been studied with very severe von Willebrand's disease; none of the Factor VIII-related properties increased despite two infusions of epinephrine. Bleeding times were normalized or remained normal in the two patients whose von Willebrand factor activity was greater than 25 U/100 ml. It remained prolonged in those three patients whose von Willebrand factor activity levels remained below that concentration. The increase in procoagulant activity was transient in all patients and $t_{\frac{1}{2}}$ values were estimated to be between 0.8 and 3.4 h.

INTRODUCTION

Most patients with von Willebrand's disease (VWD)¹ have reduced plasma levels of antihemophilic factor pro-

coagulant activity (VIII_{AHF}), antihemophilic factor antigen (VIII_{AGN}), and von Willebrand factor activity (VIII_{VWF}) (1). In addition, patients with VWD generally manifest abnormal bleeding times, diminished retention of their platelets to glass bead filters, and a characteristic delayed response to transfusion with plasma or antihemophilic factor (Factor VIII) concentrates (2–7).

Although it has both practical and conceptual importance, the cause of the sustained rise in VIII_{AHF} after transfusion in VWD, greater than that calculated from the quantity of VIII_{AHF} transfused, is not understood (4–7). Previous studies have suggested that this posttransfusion VIII_{AHF} has physicochemical (8) and procoagulant (4–7) properties like those of normal plasma Factor VIII. While susceptible to inactivation by both human and rabbit anti-Factor VIII antibodies (9), it has been reported that the "stimulated Factor VIII" does not precipitate with rabbit anti-Factor VIII (9, 10), an observation which suggests an incomplete Factor VIII may be produced in these patients. Studies in our laboratory (11) and elsewhere (10, 12, 13), have shown variable responses after transfusion of plasma or cryoprecipitate in these patients, however; these differences may reflect differences in the nature or quantity of infused materials or, perhaps, inherent variability among patients with VWD.

VIII_{AHF} rises in response to a variety of acute and chronic stimuli in patients who do not have VWD (14–

This work was presented in part at the 17th Annual Meeting of the American Society of Hematology, Atlanta, Ga., 1 December, 1974, and appeared in abstract form in *Blood*. 44: 907. 1974.

Received for publication 27 September 1975 and in revised form 27 January 1976.

¹Abbreviations used in this paper: Factor VIII (antihemophilic factor, AHF), general term for the plasma protein; VIII_{AGN}, antigen which precipitates with rabbit antibody prepared against human factor VIII; VIII_{AHF}, clot-

promoting activity of factor VIII; VIII_{VWF}, von Willebrand factor, identified in plasma as the activity which supports the aggregation of washed platelets by ristocetin (1); VWD, von Willebrand's disease.

26). A proportional increase in VIII_{AGN} has usually been identified (21–24), although discrepancies have been noted in liver disease (25, 26), renal disease associated with uremia and myocardial infarction (26), where disproportionately high levels of VIII_{AGN} have been demonstrated in some, but not all, cases. VIII_{AHF} rises in patients with VWD in response to exercise or adrenaline, (15–17), as it does in normal individuals (14–16, 18–24), but there is no information regarding VIII_{AGN} or VIII_{VWF} in these patients.

We report here studies of VIII_{AHF}, VIII_{AGN}, and VIII_{VWF} in patients with VWD given infusions of epinephrine hydrochloride in an attempt to characterize the “stimulated AHF” under conditions which are not complicated by the presence of exogenous plasma proteins. They demonstrated that epinephrine induces a marked increase in VIII_{AHF}, with a lesser rise in VIII_{AGN} and VIII_{VWF} in some patients with mild and moderate VWD; no response was detected in severe VWD.

METHODS

Patients with known VWD and normal cardiovascular and renal function were hospitalized on the Lawrence Kyle metabolic ward of the Walter Reed Army Medical Center or at the University of Connecticut Health Center. Complete bed rest was enforced during the study and patients were prohibited from smoking, ingesting coffee, tea, cocoa, or other caffeinated beverages. All patients were instructed to avoid the use of oral contraceptive agents, corticosteroids, or other agents known to affect VIII_{AHF} levels (7). Informed consent was obtained from all patients and the protocol was approved by the human experimentation committees of both medical centers.

Patients were sedated with 100 mg of secobarbital the evening before the study. All blood samples were obtained with the patients in the supine position utilizing a no. 19 gauge scalp vein needle and polypropylene syringe. A slow infusion of 5% dextrose in water was maintained through the needle to keep it patent and 7 ml of blood-glucose solution was discarded before drawing each specimen.

Epinephrine hydrochloride (Parke, Davis and Co., Detroit, Mich.) in 23.4–77 ml of 0.9% saline, a total dose of 0.0042 mg/kg, was infused at a constant rate by infusion pump (Harvard Apparatus Co., Inc., Millis, Mass.) over 30 min. A mean pulse rate increase of 33 beats/min was observed and systolic pressure increased 38 mm Hg. Cardiac rhythm was monitored throughout the experiment and symptoms were limited to mild anxiety, palpitations, and peripheral vasoconstriction. A brief period of atrial-ventricular dissociation was noted in one patient (H. E.) but disappeared immediately upon discontinuation of the infusion. No other dysrhythmias were noted.

Blood was collected into a buffered citrate solution containing 0.1 M sodium citrate (three parts) and 0.1 M citric acid (two parts) with a pH of 5.1 (nine parts blood: one part anticoagulant) in polypropylene tubes (Falcon Plastics, Oxnard, Calif.) and immediately centrifuged (12,500 g) at 4°C for 20 min. Citrated plasma was assayed immediately for VIII_{AHF} by a modification of the one stage activated partial thromboplastin time assay (27) utilizing Platelin-Plus-Activator (General Diagnostics, Morris Plains, N. J.) and

naturally deficient substrate on a Clot-Tek clot timer (Hyland Div., Travenol Laboratories, Inc., Costa Mesa, Calif.) as previously described (28). Sample plasmas for other assays were frozen immediately in dry ice and acetone and stored at –70°C. VIII_{AGN} and VIII_{VWF} were determined on frozen samples by radioimmunoassay (29) and the washed platelet–ristocetin (Abbott Laboratories, North Chicago, Ill.) assay (1). Bleeding times were determined by the method of Mielke et al. (30); the normal range in our laboratory is 2–6 min. Plasma samples containing the post-infusion peak VIII_{AHF} levels were chromatographed on 6% agarose (Bio-Gel A5M, Bio-Rad Laboratories, Richmond, Calif.) using a 1.6 × 28-cm column (Pharmacia Fine Chemicals, Inc., Piscataway, N. J.) at an elution rate of 20 ml/h. 2-ml fractions were collected using barbital-saline (7.3 g NaCl, 2.76 g barbital, 2.06 g Na barbital/liter, pH 6.8) as the eluting buffer. VIII_{AHF} in column fractions was determined by the method of Breckenridge and Ratnoff (31). All assays of the Factor VIII properties (VIII_{AHF}, VIII_{AGN}, VIII_{VWF}) are expressed as units/100 ml. A frozen pool prepared from plasmas from 20 individuals with no history of bleeding disorders was used as standard in these studies and is designated as having 100 U/100 ml of each property.

The sucrose density gradient methods have been described (32). Briefly, 13.5 ml continuous 10–40% sucrose density gradients were prepared in imidazole-saline (0.02 M imidazole, 0.14 M NaCl, pH 7.4). Whole plasma (0.75 ml) was applied to gradients which were centrifuged for 27 h at 201,800 g at 4°C using an SW 40 head. Recovery of VIII_{AHF} and VIII_{AGN} exceeded 75%. Samples were assayed for VIII_{AHF} at 1:6 dilutions or greater (32).

RESULTS

Table I summarizes the clinical and laboratory features of the five patients who have been studied. One patient (W. H.) had mild clinical bleeding with only a modest increase in bleeding after surgical challenge. Three (D. K., M. H., and C. P.) had evidence of moderate clinical bleeding (epistaxis, menometrorrhagia, and transfusions after minor surgical procedures) and one (H. E.) had clinically severe bleeding (spontaneous hemarthroses). Except in H. E., the severity of the bleeding disorder did not correlate well with the levels of the several components of the Factor VIII complex.

The response to epinephrine infusion was similar in patients W. H. (Fig. 1) and D. K. (Fig. 2). An immediate and transient rise of VIII_{AHF}, VIII_{AGN}, and VIII_{VWF} was noted and the peak values of each were approximately four times the basal levels. The three values fell rapidly after the epinephrine infusion was discontinued. The estimated $t_{\frac{1}{2}}$ values for VIII_{AHF} were 3.1 h (W. H.) and 1.6 h (D. K.). The bleeding time became normal in patient D. K. for approximately 1 h, the greatest shortening, to 4 min, being noted immediately after the epinephrine infusion. The bleeding time remained greater than 20 min in patient W. H.

Somewhat greater increase in VIII_{AHF} than in VIII_{AGN} or VIII_{VWF} was noted after epinephrine infusion in patients M. H. (Fig. 3) and C. P. (Fig. 4), both of whom had equivalent levels of VIII_{AHF} and VIII_{AGN} before epi-

TABLE I
VWD Patients

Patient	Age:Sex	VIII _{AHF}	VIII _{AGN}	VIII _{VWF}	Bleeding time (min)	Severity of clinical disease
		U/100 ml	U/100 ml	U/100 ml		
W. H.	27:Male	23	6	5	>20	Mild (bleeding after tooth extraction).
D. K.	27:Female	30	8	<5	10	Moderate (Menometrorrhagia; bleeding after tooth extraction requiring transfusion).
M. H.	41:Female	47	30	43	6	Moderate (Bleeding requiring transfusion after minor surgery; epistaxis).
C. P.	26:Female	8	8	<10	>20	Moderate (Intense menometrorrhagia).
H. E.	41:Male	<1	<1	<10	>20	Severe (Spontaneous hemarthroses, etc.).
Normal range		50-155	60-168	55-130	2-6	

FIGURE 1 Antihemophilic factor (Factor VIII) procoagulant activity (VIII_{AHF} ●—●), antigen (VIII_{AGN} ○—○), and von Willebrand factor activity (VIII_{VWF} △—△) after epinephrine infusion in patient W. H. The plasma levels of each of these three properties are indicated on the vertical axis. Pooled normal plasma (100 U/100 ml) is the standard for each assay. Three "base-line" plasma samples were obtained with the intravenous needle in place before infusion of epinephrine. The bleeding time was recorded as >20 min before the infusion, immediately after the infusion and 45 min later.

nephrine infusion. C. P. (Fig. 4) had an immediate 10-fold rise of VIII_{AHF} but minimal response of VIII_{AGN} or VIII_{VWF}. Although all Factor VIII-related measures rose after epinephrine infusion in M. H., the magnitude of the VIII_{AHF} increase (ninefold; from 45 to 400 U/100 ml) and the VIII_{VWF} increase (eightfold; from 32 to 256 U/100 ml) was greater than that for VIII_{AGN} (fourfold; from 35 to 138 U/100 ml). The duration of VIII_{AHF} elevation in these two patients was also brief; estimated $t_{1/2}$ values were 3.4 h in M. H. and 0.8 hours in C. P. The bleeding time was normal before epinephrine infusion in

FIGURE 2 VIII_{AHF} (●—●), VIII_{AGN} (○—○), and VIII_{VWF} (△—△) after epinephrine infusion in patient D. K. The bleeding time was 10 min before the infusion (N = 2-6), 4½ min immediately after the infusion, 4 min at 15 min postinfusion, 17 min at 1 h, and >20 min at 2 h postinfusion.

FIGURE 3 $VIII_{AHF}$ (●—●), $VIII_{AGN}$ (○---○), and $VIII_{VWF}$ (△—△) after epinephrine infusion in patient M. H. The bleeding time was 2 min before infusion and was unchanged immediately after infusion.

M. H. and no other determinations were carried out. The bleeding time remained longer than 20 min in C. P.

Patient H. E. (Fig. 5), whose $VIII_{AGN}$ level was less than 1 U/100 ml, was the most severely affected patient tested. No changes in $VIII_{AHF}$, $VIII_{AGN}$, or $VIII_{VWF}$ could be detected after two separate epinephrine infusions and the bleeding time remained long (greater than 20 min).

An estimate of the molecular size of the "stimulated $VIII_{AHF}$ " was obtained by agarose gel chromatography and sucrose density gradient ultracentrifugation of plasma samples stored at -70°C for 2–8 wk. Fig. 6 illustrates the chromatographic patterns found on the peak postepinephrine infusion samples of patients W. H. and D. K. Both $VIII_{AHF}$ and $VIII_{AGN}$ were eluted in the void volume fractions indicating a molecular weight of greater than 1.0×10^6 daltons. This elution pattern is the same as that previously reported for normal plasma $VIII_{AHF}$ (33). A preliminary sucrose density centrifugation study has also been carried out with a postepinephrine infusion sample of patient D. K. The "stimulated $VIII_{AHF}$ " was found in the same fractions as $VIII_{AHF}$ in normal plasma, i.e. fractions which correspond to molecular weight of greater than 1.0×10^6 (32).

DISCUSSION

The response to transfusion of patients with VWD has intrigued observers since the initial description by Nilsson and co-workers in 1959 (4). Despite variability in response to transfused plasma among some patients with VWD (34), and a degree of overlap with normal individuals (35), the delayed peak and slower disap-

FIGURE 4 $VIII_{AHF}$ (●—●), $VIII_{AGN}$ (○---○), and $VIII_{VWF}$ (△—△) after epinephrine infusion in patient C. P. The bleeding time was >20 min before infusion and remained >20 min at 15 min, 30 min, 1 h, and 2 h after the infusion.

pearance of $VIII_{AHF}$ after plasma transfusion has been considered characteristic of this disease (4–6). The control mechanisms of this response, however, and the nature of the "stimulated $VIII_{AHF}$ " remain uncertain. Although Barrow and colleagues did not detect physicochemical differences between normal $VIII_{AHF}$ and "stimulated $VIII_{AHF}$ " from a patient with VWD (8), recent studies have described rather marked in vitro lability of $VIII_{AHF}$ when VWD plasmas are stored for short periods at -20°C (10, 36). Additionally, immunochemical methods have demonstrated that plasmas with "stim-

FIGURE 5 $VIII_{AHF}$ (●—●), $VIII_{AGN}$ (○—○), and $VIII_{VWF}$ (△—△) after epinephrine infusion in patient H. E. The bleeding time was >20 min before the infusion and remained >20 min immediately after the infusion, and at 3 h after the infusion.

FIGURE 6 Chromatographic pattern of the peak postepinephrine infusion samples of patients W. H. and D. K. $VIII_{AHF}$ (●—●), $VIII_{AGN}$ (▲---▲) and protein concentration, OD 280 (Δ---Δ) are indicated on the vertical axes. Fraction numbers are plotted on the horizontal axis (2 ml fractions). 2 ml of plasma from W. H. (containing 52 U of $VIII_{AHF}$ /100 ml) and 1.4 ml of plasma from D. K. (containing 96 U of $VIII_{AHF}$ /100 ml) were applied to the agarose columns.

ulated $VIII_{AHF}$ ” do not have corresponding levels of $VIII_{AGN}$ when measured by immunoprecipitation methods using rabbit antibodies (9, 10). These observations have led to the suggestion that the “stimulated $VIII_{AHF}$ ” is indeed different from normal plasma $VIII_{AHF}$. Transfusion experiments are difficult to interpret, however, because of the variable responses to different therapeutic

materials (37) and the possible effects of plasma proteins other than factor VIII.

Previous studies have identified an increase in Factor VIII procoagulant activity ($VIII_{AHF}$) in VWD patients given epinephrine (15, 16), a rise which is more rapid and transient than that which follows plasma transfusion (4-6). We have confirmed the rapid response

to epinephrine in this disease and have also identified an increase in VIII_{AGN} and VIII_{VWF}. The rapid increase of all three properties after epinephrine infusion suggests that epinephrine stimulates the release of preformed Factor VIII rather than new synthesis. Moreover, it is clear that no exogenous protein intermediate is required for the release of VIII_{AHF}, VIII_{AGN}, or VIII_{VWF}. The identification of VIII_{AGN} in endothelial cells by immunofluorescence (38, 39), and the detection of both VIII_{AGN} and VIII_{VWF} in the media of cultured human endothelial cells (40, 41), suggests that the rapid effect of epinephrine may be due to Factor VIII release from endothelial cells. This interpretation is supported by the identification of VIII_{AGN} in endothelial cells of superficial veins obtained by biopsy in patients with mild or moderate VWD (42). The failure to detect an epinephrine effect in patient H. E. is also consistent with this hypothesis, for VIII_{AGN} was not detected in endothelial cells of patients with severe VWD (42). Based on these studies, it is conceivable that pharmacologic manipulation of Factor VIII release may be accomplished in the future without supplying exogenous plasma proteins. Long acting vasoactive drugs may be useful in the support of patients with VWD during short term surgical procedures or in the management of limited trauma. Further investigation of the mechanism of the in vivo response of Factor VIII to pharmacologic agents seems warranted.

The bleeding time remained prolonged in two of the patients studied (W. H. and C. P.) even though VIII_{AHF}, VIII_{AGN}, and VIII_{VWF} levels were increased after epinephrine infusion. Previous studies of the relationship of the bleeding time to VIII_{VWF} suggest that a normal bleeding time indicates VIII_{VWF} levels above a critical value estimated to be between 20 and 40 U/100 ml (1, 43). The VIII_{VWF} (and VIII_{AGN}) levels remained below 25 U/100 ml during the postinfusion period in both W. H. and C. P.; the persistently prolonged bleeding time in these patients is consistent with previous studies of this relationship (1, 43). In contrast, the bleeding time shortened from 10 to 4 min after epinephrine infusion in D. K. as the VIII_{VWF} level rose to 32 U/100 ml. The correlation of bleeding time correction and VIII_{VWF} levels in D. K. differs from the findings reported by Ratnoff and co-workers for two patients with VWD. In each of these individuals the bleeding time remained long even though VIII_{AHF} and VIII_{AGN} rose to normal levels and the platelets aggregated normally with ristocetin (44, 45). These contrasting observations indicate the need for further careful studies of the relationship of the bleeding time and VIII_{VWF} levels in VWD.

The apparent in vivo difference in the VIII_{AHF} response from that of the VIII_{AGN} and VIII_{VWF} in patient C. P. (Fig. 4) must be interpreted with caution. Al-

though it is possible that epinephrine has a differential stimulatory effect on three separate entities, the nature of these assays makes it impossible to compare the different components of the Factor VIII complex in any direct way. Each property is quantified by reference to a normal plasma pool standard and only relative concentrations can be measured. If the normal plasma standard contains different numbers of molecules of the components of the Factor VIII complex, addition of material which has the same number of molecules of each component would cause variable changes in the values measured in the three assays. The different responses of the three properties would be most apparent if only a small proportion of the Factor VIII complexes in normal plasma had VIII_{AHF} activity. If this were the case, the postinfusion changes in VIII_{AHF} would be more striking if fully active molecules were released from endothelial cells by epinephrine stimulation. A similar differential response of VIII_{AHF} and VIII_{AGN} has been reported by Ruggeri and co-workers in their studies of a synthetic analogue of vasopressin. The basis for this differential response in plasma assay values was not discussed in their preliminary report (46).

We do not know how epinephrine causes changes in Factor VIII levels. Although this drug may effect the release of Factor VIII storage from sites, it is also possible that it may affect the Factor VIII molecule, either directly or indirectly. Transient thrombin generation, for example, would increase VIII_{AHF} without affecting VIII_{AGN} or VIII_{VWF}, i.e., VIII_{AHF} could be "activated" (46-49). Postinfusion VIII_{AHF} appears to be very large, however, (Fig. 6), an observation which is not consistent with the changes in the sedimentation and chromatographic properties which have been described for thrombin-activated Factor VIII (50, 51). Further assessment of the possible role of thrombin generation during epinephrine infusion and of the properties of the "stimulated AHF" are in progress.

The pattern of Factor VIII related measurements after epinephrine infusion in C. P. (Fig. 4), normal VIII_{AHF} with very low VIII_{VWF} and VIII_{AGN}, is similar to that which has been identified after plasma or cryoprecipitate infusion in VWF (9, 10). Material which has VIII_{AHF}, and which has very low VIII_{AGN} and VIII_{VWF} levels, has also been identified in in vitro studies in which Factor VIII is exposed to high ionic strength buffers (32, 47). Although this similarity is of great interest, its significance is uncertain. Since VIII_{AHF} obtained in high salt separations appears to have a lower molecular weight than the other components of the Factor VIII complex, we have examined the properties of "stimulated VIII_{AHF}" on agarose gel chromatography and sucrose density gradient centrifugation. Although we have not identified any low molecular weight VIII_{AHF} in

these studies, it is important to recognize the inherent problems in determining VIII_{AHF} size. It is possible that the properties of postinfusion VIII_{AHF} are modified by the association of low molecular weight material with the larger components of the factor VIII complex which are present in these plasmas. It is also possible that there is aggregation of "stimulated VIII_{AHF}" during storage and/or in vitro analysis.

The different patterns of response to epinephrine in these patients may correspond to differences in the molecular defects which are responsible for VWD. In the most severe form of the disease (patient H. E.), no Factor VIII could be detected, even after epinephrine stimulation; this may represent an absolute defect in synthesis. Reduced but measurable quantities of the components of the Factor VIII complex are present in patients with mild and moderate VWD. The increases detected after epinephrine stimulation suggest that some control mechanisms are present in these individuals, however, and that they are susceptible to pharmacologic modification. The relationship of this modification to possible treatment of VWD remains to be determined.

ACKNOWLEDGMENTS

The authors wish to thank Mrs. Carol Church, Miss Norma Trabold, Mr. Carl Carta, and Mr. Charles Barr for excellent technical assistance. We thank Dr. Robert T. Breckenridge for referring patient H. E. for study.
