Summary

Cardiac abnormalities are the most common birth defects. Derangement of circulatory flow affects many vital organs; without proper supply of oxygenated blood, the brain is particularly vulnerable. Although surgical interventions have greatly reduced mortality rates, patients often suffer an array of neurological deficits throughout life. Neuroimaging provides a macroscopic assessment of brain injury, and has shown that white matter is at risk. Oligodendrocytes and myelinated axons have been identified as major targets of white matter injury, but still little is known about how congenital heart anomalies affect the brain at the cellular level. Further integration of animal model studies and clinical research will define novel therapeutic targets and new standard of care to prevent developmental delay associated with cardiac abnormalities.

Keywords

congenital; heart; white matter; myelin; oligodendrocyte

Why congenital cardiac anomalies and white matter injury?

Congenital heart disease (CHD) is the most common major birth defect; nearly 8 in every 1000 infants born each year suffer a cardiac abnormality [1]. Although significant advances have greatly reduced hospital mortality risk [2], patients with CHD frequently suffer from a broad spectrum of subsequent neurological deficits; including motor, cognitive, behavioral, social, and attention abnormalities [3–6]. Due to improvements in the mortality rate, it is estimated that 1 in every 150 young adults will be affected by some form of CHD within the next decade [7]. The personal, familial, and societal costs/hardships of neurological morbidity within this expanding population are inestimable. Therefore, as stated by the Pediatric Heart Network of the National Heart, Lung, and Blood Institute [8], "one of the most important challenges in the 21st century for CHD patients is to improve neurological deficits."

[*]Corresponding author: Gallo, V. (vgallo@cnmc.org).

Neurological outcome in CHD patients is governed by multiple factors, including unusual fetal cerebral blood flow and oxygen saturation [9]. In normal fetuses, highly oxygenated blood is preferentially streamed to the developing brain; however, severe/complex CHD often alters blood flow (Figure 1), resulting in delivery of de-saturated blood to the brain [9,10]. These alterations have been shown to cause immature and delayed brain development in newborns [11–15]. Recent MRI studies demonstrate a high frequency of white matter (WM) injury (25–55%) in CHD patients [14,16–18]. In addition to the prenatal insults to WM development, clinical trials and animal models have identified peri-operative factors - such as cardiopulmonary bypass surgery - contributing to brain injury [17,19–22]. Cellular events associated with CHD-induced WM injury are largely unknown and unexplored, partially due to the technical and ethical difficulties of studying human tissue. Although several large and small animal models have been designed to mimic CHD, they are rarely utilized to study the impact of CHD on WM development, particularly at the cellular level. The purpose of this review is to summarize current knowledge in this field and highlight an urgent need to create a truly translational area of research in CHD-induced WM injury through further exploration and integration of animal models with findings in human subjects and in postmortem human tissue.

Congenital heart disease (CHD)

Worldwide, approximately 1.3 million infants are born with CHD each year and this population is steadily rising [23]. More than 75% of CHD children who survive the first year of life, including those with complex cardiac malformations, will live into adulthood [24]. Prolonged neurological deficits are commonly observed in patients with CHD and pose substantial socioeconomic and management challenges for patients, families, and society. Elucidating the cellular events underlying CHD-induced neurological deficits is not only a fundamental research endeavor: it is vital for the healthcare of this growing community of patients.

Several complex factors, often combinatorial and cumulative, contribute to neurological outcomes in patients with CHD (Figure 1), including: i) preoperative factors, such as unusual fetal cerebral blood flow; ii) perioperative factors involved with heart surgery; and iii) postoperative factors, such as length of hospital stay and parental stress [4,19,25]. Sophisticated imaging techniques are bringing prenatal events associated with neurological injury into focus [4,10]. Fetal cerebral blood flow involves preferential streaming of the most highly oxygenated blood to the developing brain [9]. However, heart abnormalities can alter these beneficial patterns, resulting in less or oxygen-deficient cerebral blood flow [9,10] (Figure 1). The first organ to form during embryonic development is the heart; through shared morphogenic programs, there is great time overlap between heart and brain development in human fetuses (for review, see [14,26]). Since the heart is nearly fully developed by the 7th week of gestation, cardiac abnormalities can disrupt fetal cerebral oxygen and nutrient delivery for more than 7 months during a period critical for brain development.

In order to survive, a majority of newborns with severe/complex CHD require cardiac surgery within the first few weeks of infancy. Since surgery cannot be performed on a

beating heart it is necessary to stop the heart during cardiopulmonary bypass surgery (CPB) - a technique involving mechanical circulation and oxygenation of blood throughout the body while bypassing the heart and lungs. Although CPB facilitates heart surgery, this process mounts an inflammatory response associated with WM injury to the developing brain [27,28]. In addition to CPB, surgical correction of complex congenital cardiac anomalies may also require deep hypothermic circulatory arrest (DHCA). During this procedure the body is cooled to 15–18°C and blood circulation is completely stopped, which carries a risk of hypoxic/ischemic and reoxygenation injuries to the brain. Cardiac surgery itself introduces additional and compounding insults to the developing brain including gaseous and particulate microemboli.

To understand mechanisms underlying neurodevelopmental impairments in patients with CHD, it is imperative to fully investigate cellular events within the brain associated with CHD and corrective surgery. Understanding the combinatorial nature of these etiologies is also necessary for the development and improvement of treatment strategies for CHD.

Outcomes of CHD-induced brain injury: from conception to adolescence

Nearly all serious congenital cardiac abnormalities can be detected prenatally in the United States, and preoperative neurodevelopmental impairments are identifiable within days of birth [14,29]. In neonatal and early infant periods, motor asymmetries, absent suck, feeding difficulties, hyper- and hypotonia, poor visual orientation, and unusual cranial sizes are amongst the visible abnormalities that will likely result in neurological impairments later in life [9,30,31]. Following surgery for CHD, prospective clinical trials and retrospective clinical studies have documented worse outcomes for motor skills than cognitive abilities in children 1 and 4 years of age [5,6,32]. These findings are consistent with several recent studies using magnetic resonance imaging (MRI) in newborns and infants after cardiac surgery, which - as discussed below - also documented significant evidence of WM injury.

As infants mature into childhood, a battery of advanced neurodevelopmental and neuropsychological tests can readily identify neurological abnormalities in the CHD population that cannot be assessed in neonates. Children born with complex CHD requiring surgery may exhibit motor, cognitive, and behavioral difficulties encompassing problems in a broad range of skills: visual-spatial, fine and gross motor, memory, attention, language, executive, and psychosocial [9,33,34]. The broad range of neurological dysfunction documented in CHD patients is remarkably similar to the deficits observed in preterm survivors, in whom WM injury is a major source of morbidity [35–37].

Few studies have followed the neurodevelopmental outcome of children born with a CHD into adolescence. Increasing evidence that CHD newborns are at high risk of manifesting neurodevelopmental disorders [3] has spurred a consensus to the need of continuously monitoring these patients during childhood and throughout adolescence. The neurodevelopmental outcome of adolescents born with d-transposition of the great arteries (d-TGA) who underwent surgical correction was recently reported [3]. Despite a history of special academic services and psychotherapeutic counseling, these adolescents performed significantly lower than the population mean on a battery of tests scoring academic

achievement, general memory, visual-spatial skills, social cognition, and attention [3,38]. A significant correlation between neurodevelopmental deficits in CHD patients and WM injury determined by conventional imaging techniques has not been identified [32,39]. However, a recent study demonstrated altered WM microstructure in CHD patients with diffusion tensor imaging (DTI) in regions of the brain displaying no obvious WM abnormalities by routine MRI [40]. Adolescents with CHD show a strong correlation between cognitive outcome and reduced WM microstructures assessed with DTI [41]. Additionally, a recent study reported a high incidence of depression and anxiety in adults with CHD [42].

Since WM is crucial for proper neural connectivity and communication [43], WM immaturity and injury likely account for the type and severity of neurological deficits exhibited in CHD patients. In light of findings from neurological assessments in patients with CHD, there is a clear need to define the cellular response and vulnerability to CHD-induced WM injury during critical developmental periods in order to develop therapeutic interventions to treat and promote recovery of CHD-induced WM damage.

Neuroimaging of white matter in CHD patients

Advances in neuroimaging technology have provided a wealth of information regarding brain development and injury in patients born with CHD (Box 1). Collectively, the most recent WM imaging studies in newborns have primarily focused on preoperative WM abnormalities and newly acquired WM injury patterns associated with, and following, cardiac surgery (summarized in Table 1).

Diffuse and focal (e.g. – periventricular leukomalacia) WM injury represent the predominant signatures detected by MRI in CHD patients. Over the past five years, MRI studies have demonstrated that CHD patients often exhibit WM abnormalities and immaturity at birth (Table 1). Additionally, it has become widely recognized that newly acquired WM injury from perioperative factors is one of the most prevalent lesions seen in CHD patients (Table 1). A recent clinical study reported that WM injury was the most common brain injury in infants born with various forms of CHD before (20%) and after (44%) heart surgery [17]. Although WM injury has been reported in several clinical studies, it is important to consider the multivariate nature and complexity of these studies encapsulating (i) patient demographics: most studies include a mixed population of patients with several forms of CHD (Table 1); (ii) type of surgical intervention; and (iii) perioperative procedures. Prospective MRI studies performed on patients diagnosed with the same CHD and undergoing the same surgical procedure will be of great value in determining the vulnerability of WM in the developing brain.

Until recently, the maturation process of WM in the developing fetus was unknown, due to the technical difficulty of motion artifacts during fetal MRI scans [15,44]. Using advanced fetal MRI imaging on living fetuses with hypoplastic left heart syndrome (HLHS), a progressive decline in WM brain volume from 25 to 37 weeks of gestation was seen, when compared to control fetuses [15]. Interestingly, these differences were only significant after 30 weeks gestation. This study provides strong evidence that immature WM is particularly

vulnerable in CHD patients prior to birth, and underscores the importance of imaging the brain longitudinally *in utero*.

In parallel with antenatal WM findings, CHD fetuses also display drastic delays in cortical folding, preceding a progressive decline in normal cortical and subcortical gray matter development [15]. The use of magnetic resonance spectroscopy (MRS) also demonstrates lower NAA:Cho – a measure of neuronal [metabolic] integrity – in CHD fetuses during the third trimester; a critical period with elevated oxygen demands during robust synapse formation/activity [13]. Though indirect, these findings strongly suggest the presence of CHD-induced neuronal abnormalities during fetal development.

Doppler ultrasound is an emerging technique that can predict brain volumetric abnormalities and neurodevelopmental outcomes of fetuses with certain CHDs [15,45–50]. This noninvasive technique offers important information regarding fetal hemodynamics by measuring the velocity of blood flow through cerebral arteries. CHD fetuses with lower cerebroplacental resistance (CPR < 1.0) were found to have less white, cortical gray, and subcortical gray matter volumes associated with an absence of antegrade blood flow to the developing brain [15]. Additionally, a reduction in fetal cerebral oxygen consumption correlates with smaller brain volumes in CHD fetuses [46]. Abnormal cerebrovascular resistance in the middle cerebral arteries of CHD fetuses was recently reported to precede lower cognitive development scores, assessed at 18 months of age [45]. MRI, MRS, and Doppler ultrasound offer useful measures of macroscopic brain structures/volumes, metabolic activity, and blood flow during fetal development. Routine and follow-up scans, commencing in the second trimester, will be invaluable in understanding the etiologies of CHD-induced brain injury and defining optimal windows for interventions and treatments of neurological sequelae.

The emergence of DTI has provided great insights into WM immaturity and injury in CHD patients. A DTI study recently demonstrated that delayed WM development was directly correlated with abnormal cardiac anatomy associated with reduced brain perfusion in term infants with CHD [51]. Another study reported lower FA values in several WM tracts within the brains of CHD infants, including optic radiations, corticospinal tracts, corpus callosum, and the internal capsule [52]. WM microstructure in the brains of adolescents following the arterial switch procedure to correct d-transposition of the great arteries has also been explored [40]. With DTI, this group demonstrated significantly lower FA values within 18 regions of WM underlying the cerebrum and cerebellum; importantly, only scant WM injury was seen with conventional MRI in this cohort [40]. These findings highlight the need for more sensitive imaging acquisitions in CHD patients in order to better understand the manifestation of specific, associated neural deficits.

Although neuroimaging studies have provided a wealth of knowledge regarding WM injury, there is an urgent need for further, more detailed investigations. It is becoming increasingly evident that MRI scans of CHD patients have a similar signature/pattern to those of the preterm brain [53]. Future studies with DTI and refined imaging techniques will greatly aid in acquiring a full picture of WM immaturity and newly acquired injuries on the microstructural level within specific WM tracts. Additionally, follow-up studies on

postmortem CHD tissue will fuel investigations of how CHD affects WM at the cellular level; for example, DTI imaging paired with histological analysis.

The recent surge in animal imaging technologies offers several avenues for elucidating the multifactorial etiologies underlying brain impairments within the CHD population. Animal models allow for controlled conditions, such as genetic background, as well as a wide array of experimental approaches unfeasible or unethical in human patients. Unlike postmortem human tissue, euthanasia by perfusion in animals allows for rapid fixation of brain tissue to visualize microscopic changes to pathological insults at precise, static time points. Thus, there is a solid need for animal studies incorporating clinically relevant imaging approaches paired with high quality histological analysis of the cellular/molecular responses to CHD-induced brain injury. Studies of this nature will expedite, inform, and guide future clinical research in order to improve the neurological outcome of CHD patients.

The white matter: before and after

WM accounts for 50% of human brain volume. WM growth is a complex, multi-staged process during human brain maturation [43]. A primary constituent of WM is myelin, a lipid-rich membrane synthesized by specialized cells called oligodendrocytes. Myelin sheaths encase and insulate axons, which not only provides protection from their extracellular environment, but also enables efficient axonal communication. Additionally, myelin integrity is crucial for proper cognitive stability [54,55]. In humans, the onset of myelination is near midgestation; a surge of WM maturation persists into the second year of life. WM development and maintenance continue throughout adulthood [56].

Specialized imaging techniques - such as myelin water fraction imaging - have recently revealed the spatio-temporal patterns of normal WM development in humans throughout infancy and early childhood [57,58]. WM development occurs at different rates within each hemisphere and structure of the maturing brain. For example, myelination is robust in structures such as the cerebellum 3–4 months following birth, and more prominent in the frontal and temporal lobes around 6–8 months of age [57]. Hence, certain WM tracts in CHD patients are likely more vulnerable to operative factors depending on the age and time of surgical intervention.

The cellular events underlying myelination are well established and involve incremental stages of oligodendrocyte (OL) genesis and maturation (for review, see [59,60]). Oligodendrocyte precursors (OPCs) have the capacity to self-renew, and – after birth - primarily originate from the largest germinal zone of the postnatal mammalian brain, the subventricular zone (SVZ). Following cellular expansion, OPCs migrate into the WM where they undergo differentiation and myelination. Following WM injury, OPCs display a remarkable endogenous recovery potential, which recapitulates many of the processes during normal WM development ([61,62]; see below).

WM maturation delays and injury are frequently seen in CHD patients (Table 1). In order to understand the association between WM damage caused by CHD in humans, it will be necessary to understand WM injury at the cellular/molecular level. OLs simultaneously myelinate several axons, therefore loss of a single OL can have widespread effects on neural

connectivity and communication. This can also impact axonal function, ultimately resulting in severe neurological impairment.

Animal models of CHD

Multiple animal models have been developed in order to mimic congenital heart abnormalities (Table 2), and determine the underlying causes and subsequent effects of these complex birth defects. These models encompass three broad categories: (i) genetic, (ii) environmental, and (iii) surgical. Since environmental factors can be readily explored in both models, we will focus on the genetic and surgical aspects to highlight the complementary nature of small and large animal studies.

Mouse models provide significant advantages: low cost, large litter sizes, genetic and molecular manipulation, and an eclectic toolkit of cutting edge techniques. More than 750 genetic syndromes have been associated with CHD patients [34], and a vast majority of mouse CHD models rely on manipulation or deletion of a single gene (Table 2). The primary aim of these studies has been to model the structural anomalies of the heart exhibited in CHD patients. Targeting genes within cardiac neural crest precursor cell pools has been a common approach and results in several types of developmental heart defects. Interestingly, both the heart and brain largely originate from a shared ancestral pool of cells [14] and craniofacial abnormalities are commonly associated with structural abnormalities of the heart in rodent models (Table 2).

Unlike humans, WM development within the mouse brain begins postnatally [63,64]. However, nearly all genetic mouse models of CHD result in embryonic lethality; therefore, the pathological effects of CHD on WM maturation cannot be assessed in these models. Additionally, these genetic alterations typically perturb/impair the development of several vital organs in addition to the structural alterations of the heart, such as the lungs. Therefore, in order to better understand the neurological deficits seen in CHD patients, it is necessary to develop a conditional rodent model in which only cardiac defects are apparent *in utero* and allow proper birth and postnatal development.

Recently, it was demonstrated that the *Galnt1* gene is necessary for normal heart valve development and proper cardiac function in mice [65]. Although this study uncovered several of the cellular and molecular mechanisms underlying the formation and remodeling of heart valves, it holds great promise for putative brain abnormalities. Nearly 75% of *Galnt1* null mice survive into adulthood with little evidence of abnormalities in other organs (Table 2). Future studies focused on white matter development in the brains of these mice will likely provide vast insights into the cellular and molecluar mechanisms underlying brain immaturity and injury in CHD patients.

Large animals, such as swine and lambs possess a developmental WM profile similar to humans and are large enough to undergo prenatal surgery [21,66–68]. Bilateral carotid artery occlusion models in sheep fetuses to induce cerebral ischemia have provided great insights into WMI, both on a macrostructural and cellular level [69,70]. It was recently demonstrated that prenatal cerebral ischemia impairs cortical growth associated with disturbances in dendritic arborization and synapse formation in sheep [70]. Another study

reported a reduction in pre-myelinating OLs and arrested preOL differentiation localized to gliotic lesions in a sheep model of cerebral ischemia [69]; importantly, the histological findings strongly correlated with WMI detected by MRI.

Although large animal models are informative, powerful approaches to understanding the brain pathology of CHD, studies in these species have been largely limited to surgical approaches and systemic outcomes. Several groups have investigated how intra- and post-operative factors affect subsequent development, utilizing open-heart surgery approaches commonly performed to correct CHD (Table 2). Although there has been great success in emulating the surgical repair of CHDs in large animal studies, the post-operative neurological outcome was rarely assessed.

Considering the prevalence of WM developmental delays and injury in CHD patients, the near absence of knowledge and lack of emphasis on cerebral WM in animal models is alarming. While rodent models provide explanations of abnormal heart development, these studies are greatly limited by the longevity of subjects. On the other hand, large animal models have the potential to explore the peri- and post-operative vulnerability of cerebral WM during and following corrective surgery, respectively. For these reasons, there is still a scarcity of knowledge regarding CHD-induced WM impairment. Integrative approaches, capitalizing on the strengths of these complementary models will greatly aid in unveiling the underlying mechanisms resulting in the neurological impairments seen in infants born with a CHD and surviving heart surgery into adulthood.

Cellular and developmental analysis of WM injury in CHD

Our labs recently developed a cardiopulmonary bypass (CPB) surgery model in healthy neonatal piglets to assess the intraoperative contributions to WM injury [21]. WM maturation in piglets is area-dependent and greatly mirrors the progression seen in humans [21]. CPB-induced ischemia-reperfusion and reoxygenation injury demonstrated maturation-dependent vulnerability of WM; particularly, immature WM was most vulnerable. Histological analysis aimed at identifying different developmental stages of the oligodendrocyte lineage revealed a selective vulnerability of $O4^+$ preoligodendrocytes (pre-OL) (Figure 2) [21]. Oligodendrocyte precursor cells (OPCs), however, displayed great resilience to the surgical insult and represent the endogenous recovery potential of WM tissue based on their potential to generate new oligodendrocytes. An arrest in OL maturation - paired with delayed myelination - was evident one month following surgery [21]. Additionally, this study identified modifiable, perioperative measures - reduced inflammation and maintenance of high oxygen-protective of WM injury during immature stages of brain development [21].

In order to further investigate the pre- and intraoperative effects of *in utero* hypoxia and CPB on WM development and injury, respectively, we also developed a rodent brain slice model [22,71]. Mice were reared in prolonged hypoxic conditions during a neonatal developmental time window overlapping with the period spanning third trimester to term birth in humans [22]. Viable brain slices were cultured in a perfusion system with artificial CSF where circulatory arrest could be simulated simply by oxygen-glucose deprivation

(OGD). These combined approaches demonstrated pre-OL vulnerability paired with OPC resistance to insult in normal brains [22,71]. However, mature OLs and OPCs were significantly more vulnerable to OGD in brains that had developed under hypoxic conditions [22]. This shift in susceptibility to WM injury was temperature-specific and deep hypothermia during OGD was protective to OPCs [22].

Brain injury in CHD patients is remarkably similar to that seen in premature neonates. Both populations exhibit delays in WM maturation, and cardiac surgery often results in secondary WM injury. Cerebral hypoxia is an underlying commonality between these patients: in CHD patients, de-saturated blood is streamed to the brain *in utero* and following birth. After birth, premature infants often experience hypoxia due to underdeveloped lungs that cannot handle normal oxygen loads. Interestingly, studies modeling premature birth with hypoxia report similar findings to those seen in CHD models, even at the cellular level [61,62].

Proliferation and expansion of endogenous OPC pools is critical for replacing OLs and repairing damaged/absent myelin following hypoxia [61,62]. Although several key regulators of the OPC regenerative response have been identified, molecular manipulation in rodent models often relies on genetic or invasive techniques that may not be practical or ethical approaches in treating humans. Two recent studies explored the feasibility and efficacy of intranasal drug delivery to target OPCs to protect/repair WM following hypoxic or hypoxic-ischemic insults [62,72]. Intranasal infusion of human apotransferrin (aTf) prior to hypoxia-ischemia reduced WM injury and enhanced OPC survival and proliferation within the SVZ and corpus callosum [72]. Intranasal administration of heparin binding epidermal growth factor (EGF) immediately following hypoxic exposure reduced OL death, promoted OL generation, and improved functional/behavioral recovery [62].

A recent study demonstrated that OPCs are critical for the coordination of vascular growth in developing WM in mice [73]. OLs and OPCs often make direct contact with blood vessels which provide oxygen and nutrition, two key ingredients necessary for the high metabolic demand of membrane expansion during myelination. Interestingly, OPC-encoded hypoxia inducible factor (HIF) signaling was found to regulate angiogenesis while arresting OPC differentiation prior to myelination [73]. The newly formed blood vessels provide the appropriate oxygen levels to inhibit HIF activity which allows for OL differentiation and myelination in the presence of an adequate metabolic supply. These data offer a potential mechanism for delayed/arrested WM maturation in CHD fetuses; the absence of highly oxygenated cerebral blood flow stabilizes HIF activity, preventing OPC differentiation and subsequent myelination.

HIF-1α is a transcription factor that regulates several target gene products including erythropoietin (EPO) and vascular endothelial growth factor (VEGF) [74]. A recent clinical study found increased levels of HIF-1α and EPO gene expression in term newborns with CHD associated with hypoxia [74]. Erythropoietin treatment, shortly following preterm birth, has resulted in positive clinical outcomes in recent years and has promising neuroprotective potential [75–79]. Early administration of recombinant EPO (rEPO) reduced white and gray matter injury in preterm infants [75]. Additionally, follow-up studies have

shown that rEPO treatment in infancy significantly improves neurodevelopmental and cognitive outcomes in toddlers and through early adolescence [76–78].

In view of the similarities in WM and cell-specific vulnerabilities seen in CHD and preterm animal models, it is likely that there is a common mechanism of injury. Future studies modeling CHD could greatly benefit through extrapolations of findings from the enormous population of preterm birth models. Additionally, engineering and testing noninvasive or less invasive drug administration will allow for quicker translation into the clinic.

Conclusions & Future Perspectives

Over the past few decades, surgical and clinical care has significantly improved the survival rates of children born with even the most complex forms of CHD. Clinical research has recently shifted from a focus on survival to routine evaluation of morbidity throughout development [34]. As stated by the American Heart Association, the growing population of infant cardiac surgery survivors demands new unified stratification methods and algorithms to classify, diagnose, and manage developmental disorders in CHD patients [34].

Clinical trials and animal studies have provided a wealth of bidirectional information regarding the neurological impairments seen in the CHD population; however, several large gaps in knowledge remain (Box 2). While clinical studies have identified many psychological and anatomical associations between neurological defects and heart abnormalities, they are limited in technical and experimental approaches. However, such findings have guided the design of several animal models that have begun elucidating the cellular and molecular mechanisms underlying these pathologies. There is a growing need for integrative approaches, such as animal models that recapitulate clinical outcome measures while providing information on the cellular/molecular level in order to develop novel therapies.

Considering the complexity of severe CHD and the array of putative comorbidities, identifying independent causes of WM injury is difficult and will require careful study design. Infants born with d-Transposition of the great arteries (d-TGA) represent a unique avenue for integrative approaches because they typically receive surgery within 2 weeks of birth; additionally, d-TGA is rarely associated with confounding genetic syndromes seen with other anomalies [9]. With few exceptions, our neuroanatomical information regarding WM development and injury comes from clinical studies evaluating pools of patients with different types of CHD. Retrospective studies, in which patients are subdivided by specific CHD, will also be of great value.

Although large animal models are limited in genetic approaches commonly utilized in rodents, they serve as a great platform for understanding the cellular dynamics underlying CHD-induced brain injury before and after surgical intervention. Additionally, higher mammals share several anatomical, physiological, and metabolic similarities to humans and are ideal candidates for testing human drugs while closely monitoring systemic and neurological responses seen in the clinic. Banking and indexing brain tissue from CHD patients will facilitate postmortem analysis of WM injury and improve the quality of new study designs. Integrating the genetic, cellular, and molecular approaches in animal models

with novel imaging tools used on humans will mutually inform future research and provide large steps towards developing new therapies and treatment windows to improve the neurological outcomes seen in CHD patients.

Box1: Neuroimaging Techniques

Since the first computed tomography (CT) scan in the 1970s, there have been tremendous advances in neuroimaging technologies. State-of-the-art imaging techniques not only provide anatomical details but also greatly aid in surgical, stereotactic precision. These technologies vary -in cost, utility, length of scan, resolution- and have given us noninvasive longitudinal windows into abnormalities during fetal and postnatal brain development within the CHD population. Additionally, neuroimaging studies offer the promise of predictive measures in CHD developmental disorders.

Acquisition of a head ultrasound (HUS) is most common across centers, least expensive, quickest, and can identify major structural abnormalities within the brain that may worsen following cardiac surgery [34]; however, the limitations of HUS in detecting the wide spectrum of structural brain abnormalities are increasingly recognized [80]. On the other hand, Doppler imaging by HUS is still a useful tool to measure fetal cerebral blood flow [10]. This technique is also utilized as an intraoperative monitoring system to standardize cerebral oxygen delivery for the individual patient [32,81].

Over the last decade there has been an increased utilization of magnetic resonance imaging (MRI) in clinical studies and trials. Although, until recently, MRI was not a routine procedure in neonates with CHD [34] - perhaps due to clinical feasibility, cost, and safety - several prospective studies have underscored the need for brain MRIs in these children. Magnetic resonance spectroscopy (MRS) is a specialized imaging technique which provides the concentration of metabolites, such as N-Acetylaspartic acid (NAA) and choline (cho), in target brain regions. Together, these complementary techniques allow for visualization as well as metabolic activity of specific brain structures.

Recent clinical and research laboratory studies have employed more sophisticated technologies, such as diffusion tensor imaging (DTI) which enables visualization and a quantitative measure of WM microstructures. DTI is a sensitive imaging technique that measures the diffusion of water molecules and provides high-resolution images of microstructures within the brain. With diffusion tractography, WM fiber bundles can be reconstructed and quantitatively analyzed in an un-biased manner. Fractional anisotropy (FA) is a common metric of DTI and describes the directional dependence of water displacement; lower FA values are indicative of WM immaturity or injury.

Box 2: Outstanding Questions

- Can we create an animal model that recapitulates the morphogenic, developmental aspects of CHD without directly affecting other organs or developmental processes?

- What are the prenatal and neonatal cellular responses to CHD in the developing brain?

- What are the molecular mechanisms underlying WM immaturity and vulnerability to CHD and how can we intervene?

- How can we accurately assess the dynamic neurological outcomes of CHD and/or corrective surgery in animal models?

- Prenatal or postnatal insults to the developing brain: which is most devastating in regards to developmental and behavioral disabilities?

- How can we best extrapolate from, and integrate, neuroimaging findings/ correlations in human patients with cellular/molecular approaches in animal models?

Highlights

- Complex CHD is often associated with developmental delay and behavioral problems

- Currently, the neurological deficits displayed by CHD patients are irreversible

- Animal studies offer powerful avenues to understand CHD brain impairments
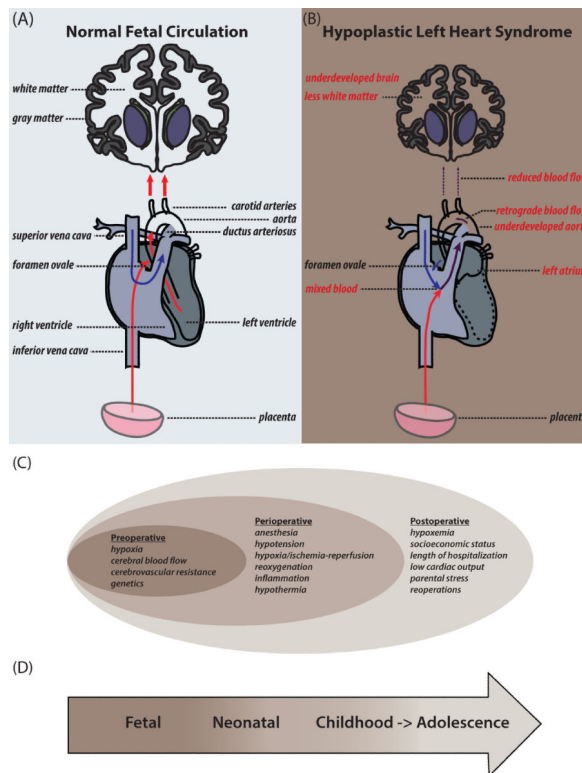

Figure 1.
Fetal cerebral circulation, white matter (WM) damage, and risk factors associated with neurological outcomes in congenital heart disease (CHD). **(A,B)** Cartoon illustrating fetal cerebral blood flow. In normal fetuses **(A)**, oxygenated blood (red arrows) from the placenta is preferentially pumped to the left heart, exits through the carotid arteries, and flows to the brain. In fetuses with hyoplastic left heart syndrome (HLHS) **(B)**, oxygenated and deoxygenated (blue arrows) blood mix (purple arrows) and is misdirected to the aorta, bypassing the carotid arteries. Retrograde flow of mixed blood exits through the carotid arteries at a low flow rate to the brain. In HLHS, developing fetal brains receive less and hypoxic blood, resulting in delayed WM maturation. **(C,D)** Risk factors associated with neurological deficits in CHD patients throughout life.
Figure 2.
Immature oligodendrocytes (OLs) are highly vulnerable to cardiac surgery-induced brain injury which delays/impairs white matter (WM) development [21]. **(A)** Gross anatomy of perinatal pig brain. **(B, C, F, G)** Immunostains labeling apoptotic (Caspase3$^+$) cells in the OL lineage within the corpus callosum (CC) 3 days following severe cardiopulmonary bypass (CPB) surgery. OL precursor (PDGFRα$^+$) and progenitor cells (Mash1$^+$, PDGFRα$^+$), as well as mature OLs (CC1$^+$), survive the surgical insult; however, immature (O4$^+$) oligodendrocytes undergo cell death (O4$^+$/Caspase3$^+$) following CPB surgery **(F)**. Fewer, mature OLs are present in the CC 4 weeks following surgery **(H)** compared to control piglets **(D)**. Additionally, less myelin (MBP) is seen the corpus callosum following injury **(I)** when compared to control animals **(E)**.

Table 1

Recent neuroimaging studies assessing white matter injury

Cohort[a]	Imaging[b]	WM Findings[c]		Refs
		Preoperative	**Postoperative**	
A. HLHS				
fetuses	MRI	• Progressive decline in WM volume from 25 to 37 weeks of gestation	N/A	[15]
fetuses	MRI	WMI (13–50%) • Prenatal diagnosis of WMI may be protective, depending on clinical practices	N/A	[82]
neonates		WMI (46–50%)		
neonates	MRI	WMI (19%) Males with aortic atresia were most vulnerable	N/A	[83]
B. Mixed				
preterm neonates	MRI	WMI (42%) • Punctate WM lesions and structural abnormalities in central WM	N/A	[84]
	DTI	• Microstructural abnormalities in the splenium of all preterm patients with CHD		
preterm neonates	DTI	• Reduced FA in cerebral WM including optic radiations and splenium	N/A	[85]
neonates	MRI	WMI (13%)	WMI (7%)	[86]
neonates	MRI	WMI (16%)	WMI (11–22%)	[16]
newborns	MRI	WMI (17%)	N/A	[87]
newborns	MRI	WMI	N/A	[52]
	DTI	↓ FA in WM tracts (optic radiations, internal capsul, corpus callosum, corticospinal)		
newborns	DTI	↓ WM FA	↓ WM FA associated with new WMI	[88]
infants	MRI	WMI (24%)	WMI (30–31%)	[89]
infants	MRI	WMI (20%)	WMI (42–44%)	[17]
infants	MRI	WMI (19%)	N/A	[80]
	HUS	• Not sensitive enough to detect same brain injuries		
infants	HUS	WMI (6%)	N/A	[90]
infants	MRI	WMI (42%)	N/A	[91]
	DTI	• Delayed WM microstructural maturation		
adolescents	MRI	N/A	WMI (11%)	[92]
C. TGA, SVP				
neonates	MRI	WMI (23%)	WMI (31%)	[93]
infants	MRI	WMI (28%)	N/A	[51]
	DTI	↓ WM FA (optic radiations, perirolandic, posterior, frontal)		
infants	MRI	N/A	WMI (28%)	[94]
adolescents	MRI	WMI (20%)	N/A	[40]
	DTI	↓FA in 18 WM regions		

Neuroimaging studies within the past 5 years.

[a]HLHS: hypoplastic left heart syndrome; TGA: transposition of the great arteries; SVP: single ventricle physiology.

[b]MRI: magnetic resonance imaging; DTI: diffusion tensor imaging; HUS: head ultrasound.

[c]WM: white matter; WMI: white matter injury; CHD: congenital heart disease; FA: fractional anisotropy.

Table 2

Recent animal models of congenital heart disease and corrective surgery

Species	WM[a]	*Gene* Protein[b]	Key Findings[c]	Refs
A. Genetic, Pharmacalogical				
Mouse	N/A	*Gata4* G295S	atrial and ventral septation defects	[95]
Mouse	N/A	*Hoxa1*	tetralogy of Fallot, interrupted aortic arch, abnormal subclavian artery	[96]
Mouse	N/A	Smad7	septal chamber defects	[97]
Mouse	N/A	RAR	second heart field and septal defects	[98]
Mouse	N/A	*Pax3*	double outlet right ventrical alignment defect	[99]
Mouse	N/A	*Galnt1*	aortic and pulmonary valve stenosis	[65]
Mouse	N/A	*FOXP1*	AVSD, HLHS	[100]
Mouse	N/A	RA, FA	TGA	[101]
B. Surgical				
Dog	N/A	N/A	surgery induced severe neurological injury and drastic increases in gene regulation	[102]
Pig	N/A	N/A	under hypothermic conditions, high pressure perfusion was not beneficial during long-term cerebral perfusion	[103]
Piglet		N/A	area- and maturation-dependent, cerebral WM injury following surgery	[21]
Piglet	N/A	N/A	higher rates of antegrade cerebral perfusion increased cerebral blood flow	[104]
Piglet	N/A	N/A	blood brain barrier permeability was increased following surgery	[105]
Piglet	N/A	N/A	ischemic preconditioning was neuroprotective following surgery	[106]
Piglet	N/A	N/A	delayed hypothermia reduced cerebral perfusion	[107]
Piglet	N/A	N/A	regional blood flow was highest in the brain following surgery with selective cerebral perfusion at 32 degrees Celsius	[108]
Piglet	N/A	N/A	intravenous injection of granulocyte-colony stimulating factor, prior to surgery, reduced pro-apoptotic signalling in the brain - especially the striatum	[109]
C. Brain slice culture				
Mouse		N/A	hypoxic exposure prior to surgery exacerbates WM injury; hypothermic conditions during surgery were protective of WM progenitor cells	[22]
Mouse		N/A	WM and WM producing cells were most vulnerable in younger mice	[71]

[a]WM: white matter; N/A: not assessed or not applicable.

[b]N/A: not applicable; RAR: retinoic acid receptor; RA: retinoic acid; FA: folic acid.

[c]AVSD: Atrioventricular septal defect; HLHS: hypoplastic left heart syndrome; TGA: transposition of the great arteries.
