Abstract

The elastic and geometric properties of arteries have been long recognized as important predictors of cardiovascular disease. This work presents a robust technique for the noninvasive characterization of anisotropic elastic properties as well as thickness and diameter in arterial vessels. In our approach, guided waves are excited along arteries using the radiation force of ultrasound. Group velocity is used as the quantity of interest to reconstruct elastic and geometric features of the vessels. One of the main contributions of this work is a systematic approach based on sparse-grid collocation interpolation to construct surrogate models of arteries. These surrogate models are in turn used with direct-search optimization techniques to produce fast and accurate estimates of elastic properties, diameter, and thickness. One of the attractive features of the proposed approach is that once a surrogate model is built, it can be used for near real-time identification across many different types of arteries. We demonstrate the feasibility of the method using simulated and *in vitro* laboratory experiments on a silicon rubber tube and a porcine carotid artery. Our results show that using our proposed method, we can reliably identify the longitudinal modulus, thickness, and diameter of arteries. The circumferential modulus was found to have little influence in the group velocity, which renders the former quantity unidentifiable using the current experimental setting. Future work will consider the measurement of circumferential waves with the objective of improving the identifiability of the circumferential modulus.

1. Introduction

The elastic properties of arteries have received significant attention in recent years as they have been identified as independent predictors of cardiovascular health (Blacher et al. 1998). Moreover, in recent years, geometric quantities such as the intima-media thickness have been also identified as early indicators of cardiovascular disease (Davis et al. 1999, Polak et al. 2011). In this regard, noninvasive methods for estimating material and geometric properties in arteries are of great current interest.

Several methods have been proposed recently for the non-invasive characterization of elastic modulus in arteries such as measurement of the speed of propagation of pressure waves

(Cockcroft et al. 2005), direct analysis of propagating modes (Bernal et al. 2011, Zhang et al. 2005, Luo et al. 2012, Konofagou et al. 2011, Luo et al. 2009, Couade et al. 2010), and inverse problem strategies based on the finite element method (Rosario et al. 2008), among others. On the other hand, the thickness of arteries is usually estimated through angiography, which is an invasive procedure, or from direct measurements in ultrasound images. The latter approach is subject to operator error and may yield significant variability of results. To the best knowledge of the authors, methodologies for the simultaneous estimation of elastic properties and thickness in arteries have yet to be developed.

The main goal of this work is to devise a fast and accurate methodology for the noninvasive characterization of anisotropic elastic properties, thickness, and diameter of arteries. To this end, in our approach, arteries are excited with ultrasound radiation (US) force and the normal particle velocity is measured along the length of the artery. The material properties and geometry (i.e. thickness and diameter) of the artery are estimated using an inverse problem solved in a constrained optimization framework. One of the main theoretical contributions of this work is the construction of surrogate models of the acoustic-structure interaction system using a sparse grid collocation approach to accelerate the inversion process. The notion is that once a surrogate is created, it can be used for the expedient reconstruction of material and geometric properties across many different arteries.

Numerical optimization approaches are becoming more frequently used for estimating material properties in biomedical applications (Aguilo et al. 2010, Oberai et al. 2003, Arridge & Hebden 1997). The main drawback of these approaches is the computational expense and complexity of implementation. For instance, finite elements are commonly used to discretize the forward problem, which has to be solved repeatedly during the optimization process. For medical diagnosis problems, such as the ones pursued in this work, minimization of computational time is highly desirable.

Different alternatives exist to decrease computational time, while maintaining accuracy in the solution of the inverse problem. For instance, model reduction approaches have been proposed and successfully used for inverse materials identification (Deng & Edwards 2007). Some approaches reduce the dimension of the approximation spaces such as those based on the Proper Orthogonal Decomposition (POD) (Brigham et al. 2007). Although POD has been successfully used to solve many important problems, one key aspect for success with POD is coming up with adequate data (i.e. snapshots) for obtaining a suitable basis for a given problem. To this end, a general and effective strategy is still needed.

Other model reduction approaches adopt a non-intrusive approach in which maps between parameter spaces (e.g. material and geometric features) and state variable spaces (e.g. displacements, velocities, etc.) are constructed (Brigham & Aquino 2007, Aguilo et al. 2010). These maps have been developed using different techniques such as neural networks, support vector machines, radial basis functions, wavelets, and polynomials, among many others (Bishop 2006). The main advantage of using this type of surrogate model is the non-intrusive nature as they can be constructed off-line. In this work, surrogate models are constructed using polynomial interpolation along with a Smolyak's sparse grid collocation strategy (Smolyak 1963, Nobile et al. 2008, Ganapathysubramanian & Zabaras 2007, Xiu &

Hesthaven 2005, Klimke et al. 2004). The main advantages of polynomial interpolation on sparse grids are readily available error estimates and ease of training. In this work, arteries will be represented as cylindrical geometries with transversely isotropic materials, allowing for low-dimensional parametric representations of both geometry and material properties.

This paper is organized as follows: Section 2 describes the forward problem, a method for calculating group velocity, the sparse grid collocation technique, and the algorithm proposed for inverse identification. In Section 3, we present numerical examples that demonstrate the performance of the method using simulated experiments. In Section 4, we present experimental results for an *in vitro* artery and a rubber tube. Finally Section 5 states the conclusions and future work.

2. Background

2.1. Forward Model

It well known that the mechanical response of the arterial wall is nonlinear with respect to changes in internal pressure. However, in the current study we will focus on waves launched by the radiation force of ultrasound. These waves are of very low amplitude and can be modeled using the linear theory of elasticity. In essence, we conceive an artery at a given state of deformation and internal pressure as a given configuration for which we will compute linearized deformations and stresses. Furthermore, we will not use a proper linearization of a nonlinear constitutive model, but a simple Hookean model. Although the latter simplification is not formal from the mechanics perspective, it is nevertheless useful from the diagnosis point of view since engineering quantities such as Young's modulus and shear modulus can be easily interpreted. We elaborate further on the diagnostic value of simplifications in Section 2.1.2.

In this work, we model an artery and the surrounding fluid as a coupled acoustic-structure interaction (ASI) dynamical system. We will not include in our model the properties of surrounding tissue and viscosity of blood as the experiments presented in a subsequent section were carried out in a water bath. Tissue and viscosity will be included in future work. The governing equations for an artery undergoing transient motion are given as

 $\rho_{s}\ddot{\mathbf{u}} - \nabla \cdot \boldsymbol{\sigma} = \mathbf{0}, \quad \text{in } \Omega_{s} \quad \text{(1a)}$ $\mathbf{u}|_{t=0} = \mathbf{0}, \quad \dot{\mathbf{u}}|_{t=0} = \mathbf{0} \quad \text{in } \Omega_{s} \quad \text{(1b)}$ $\boldsymbol{\varepsilon}[\mathbf{u}] = \frac{1}{2} (\nabla \mathbf{u} + \nabla \mathbf{u}^{\top}), \quad \text{in } \Omega_{s}, \quad \text{(1c)}$ $\boldsymbol{\sigma} = \mathbb{C}: \boldsymbol{\varepsilon}, \quad \text{in } \Omega_{s} \quad \text{(1d)}$ $\boldsymbol{\sigma} \mathbf{n}_{s} = -p\mathbf{n}_{s}, \quad \text{on } \Gamma_{fs} \quad \text{(1e)}$

$$\sigma \mathbf{n}_s = \boldsymbol{\tau}, \quad \text{on } \Gamma_t \quad \text{(1f)}$$

 $B \mathbf{u} = \mathbf{0}, \quad \text{on } \Gamma_R \quad \text{(1g)}$

where **u** is displacement, σ is the stress tensor, ρ_s is the solid mass density. The variable Ω_s represents the solid medium, which in the present case is the artery, ε is the linearized strain tensor and \mathbb{C} is the elasticity tensor. The boundary at the interface of the artery and fluid is represented as Γ_{fs} , while Γ_t is the part of the boundary where tractions are applied, and \mathbf{n}_s is a unit vector normal to the surface of the solid. The operator \boldsymbol{B} is used to represent absorbing conditions on the boundary Γ_R .

The governing equations of the acoustic medium inside and outside the artery are given as

$$\ddot{p} - \nabla^2 p = 0, \quad \text{in } \Omega_f \quad \text{(2a)}$$

$$p|_{t=0} = 0, \quad \dot{p}|_{t=0} = 0 \quad \text{in } \Omega_f \quad \text{(2b)}$$

$$\frac{\partial p}{\partial \mathbf{n}_f} = \rho_f \ddot{\mathbf{u}} \cdot \mathbf{n}_s, \quad \text{on } \Gamma_{fs} \quad \text{(2c)}$$

$$\frac{\partial p}{\partial \mathbf{n}_{rf}} = -\frac{\dot{p}}{c_f}, \quad \text{on } \Psi_{RF} \quad \text{(2d)}$$

where *p* is the fluid pressure, ρ_f is the density of the fluid surrounding the artery. Equation (2c) represents the boundary condition at the interface of the artery and the surrounding fluid and Eqn. (2d) describes the Sommerfeld radiation boundary condition on the truncated semiinfinite fluid medium. The variable Ω_f represents the fluid domain, Ψ_{RF} refers to the boundary where the radiation condition is applied, \mathbf{n}_f is a unit vector normal to the fluid surface, and \mathbf{n}_{rf} is the unit normal pointing outward of Ψ_{RF} . A schematic of the truncated artery and the surrounding fluid with the boundaries described in equations 1 and 2 is depicted in Fig. 1.

We used the Finite Element Method (FEM) to obtain approximate solutions to the coupled boundary value problems described herein. Details of the FEM for ASI problems are omitted for brevity and can be found in (Everstine & Henderson 1990).

2.1.1. Group velocity—We use group velocity measured along a path in the artery as the quantity of interest from which we identify geometric and material properties. This quantity of interest is commonly used in elasticity imaging due to its simplicity and ease of use (Bernal et al. 2011). In this section, we provide details for the calculation of group velocity from measured particle velocities along a path in an artery. Group velocity refers to the velocity with which a wave envelope propagates. In the current problem, we are interested in the group velocity of waves propagating on a path along the length of the artery.

Traveling waves along such paths are easily measured with ultrasound transducers and hence are the focus of this work.

We will define a path along the length of the artery of as a set of coordinates given as (See Fig. 1)

$$T(x, y, z) := \{r_o, 0, z\},$$
 (3)

where x, y are coordinates on the cross section of the artery and coordinate z is aligned along the length of the artery. r_o is the outer radius of the artery. We will next derive a approach to compute the group velocity along this path using the cross covariance of particle velocities.

Let $v_n(T, t) := \mathbf{u}(T, t) \cdot \mathbf{n}_s$ be the normal particle velocity at time *t* and along path *T*. The cross-correlation between two locations $T_i := \{r_o, 0, z_i\}$ and $T_j := \{r_o, 0, Z_j\}$ for a given time difference τ is obtained as

$$C_{ij}(\tau) := \frac{\int_{0}^{T} [v_n(T_i, t) - \hat{v}_n(T_i)] \left[(v_n(T_j, t + \tau) - \hat{v}_n(T_j)) \right] dt}{K} \quad (4)$$

where *T* is the total time of wave propagation, *K* is a normalizing constant such that $C_{ii}(0) = 1$, and $\hat{v}_n(T_i) := \int_0^T v_n(T_i, t) dt/T$ is the mean velocity. The time delay t_{ij}^d is defined as the value of τ that maximizes the cross-correlation between positions T_i and T_j (Viola & Walker 2005), i.e.,

$$t_{ij}^d := \operatorname{argmax} C_{ij}(\tau).$$
 (5)

The group velocity c_g is then found by solving the following least squares optimization problem.

$$c_g := \underset{v}{\operatorname{argmin}} \left\| v - \frac{\Delta z_{ij}}{t_{ij}^d} \right\|^2, \quad \Delta z_{ij} := z_i - z_j \quad (6)$$

where $\|\cdot\|$ refers to the Euclidean norm. It is important to notice that the group velocity in (6) is independent of the magnitude of the load. Hence, precise knowledge of the magnitude of the load will not be needed later on when we formulate the inverse problem. This is one of the salient features of our proposed method since it is difficult to accurately know the magnitude of the radiation force of ultrasound used in practice.

2.1.2. Parameters of Interest and Sensitivity Study—Arteries are complex vessels whose cross sections can vary along their length due to normal anatomical changes or due to disease (e.g. atherosclerosis). Furthermore, the arterial wall is composed of three layers containing collagen and elastin fibers taking different orientations across layers (Holzapfel et al. 2000). Moreover, the material response with increasing internal pressure is nonlinear. Accurate modeling of arterial behavior needs to take into consideration the latter

complexities. However, when the goal is to deduce relative changes in material and/or geometry for diagnostic purposes, simplified models can oftentimes provide very useful information. If diagnosis is the main objective, it is important to achieve a balance between model complexity and accuracy. One one hand, we want to capture the real response of arteries as close as possible, but on the other hand as model complexity increases so does the number of parameters in the model.

In the case of arteries, simple models and idealizations are commonly used and have been shown to provide useful information for differentiating between healthy and unhealthy groups (Couade et al. 2010, Davis et al. 1999). An artery model based on a circular cylinder with a single layer can be seen as a first-order approximation to a more complex model containing a variable cross section, multiple layers, and fibers oriented in multiple directions. This first-order model will be of diagnostic value as long as changes in its defining parameters correlate with the onset and progression of disease. In the case of arteries, changes in cross section can be naturally approximated as changes in diameter and thickness of cylindrical vessels. Furthermore, changes in stiffness, localized or spread across the three arterial layers, can be approximated as average changes in the mechanical properties of a single material layer. As long as material and geometric changes in this simple approximations correlate to material and geometric changes, respectively, in the real system, these coarse models can be valuable from the diagnosis point of view.

Based on the foregoing reasoning, we will assume arteries to be simple transversely isotropic cylindrical vessels. Hence, the main parameters of interest consist, in general, of five independent material moduli, diameter, and thickness. The material parameters of interest are two Young's moduli; E_L , E_C ; two Poisson ratios, v_{LC} , v_{RL} ; and one shear modulus, G_{LC} , where *L*, *C* and *R* represent longitudinal, circumferential, and radial directions, respectively (Daniel & Ishai 2006).

The geometry is described completely by its diameter (d) and thickness (h). Assuming incompressibility of the material, the Poisson ratios can be readily identified from the Young's moduli as (Bernal et al. 2011)

$$\nu_{LC} = \frac{1}{2} \quad (7)$$

$$\nu_{RL} = 1 - \frac{E_L}{2E_C} \quad (8)$$

Thus, we are left with a total of three (3) material parameters (i.e. E_L , E_C , G_{LC}) plus the diameter and thickness to be identified.

We investigated the sensitivity of the group velocity to changes in the parameters of interest to determine the identifiability of the latter through an inverse problem approach. To this end, we carried out transient finite element simulations varying each parameter over a predetermined range, while fixing all others, and computed the group velocity. Defining

 $\boldsymbol{a} := \{E_L E_C G_{LC} h D\}^T$ as the parameter vector, the sensitivity of the group velocity to changes in parameter α_i , denoted as S_{cg_i}

$$S_{cg_i} = \frac{\alpha_i}{c_{g_o}} \frac{|\Delta c_{gi}|}{|\Delta \alpha_i|} \quad (9)$$

In the above equation, a_i is the change in parameter a_i with respect to its base value, c_{go} is the value of the group velocity evaluated at the base state, and c_{g_i} is the change in group velocity corresponding to a_i . For the present case, the base state was taken as $E_L = E_C = 100$ kPa, $G_{LC} = 50$ kPa, h = 0.7 mm, and D = 6 mm. These values were decided based on previously reported experimental results (Bernal et al. 2011).

The results from our sensitivity study are reported in Table 1. We can observe that group velocity was significantly more sensitive to changes in the longitudinal modulus (E_L) , thickness (h), and diameter (D) than it was to changes in the shear modulus (G_{LC}) and circumferential modulus (E_C) . Although, the sensitivity of the group velocity to changes in E_C was very low, we decided to keep this variable in our parameters of interest to investigate the effect of lack of sensitivity of a parameter on inversions. Based on these observations, E_C , E_L , D and h were selected as the parameters of interest. Notice that since no sensitivity was observed to shear modulus, the group velocity is considered uninformative about this quantity and hence it will be excluded from the inverse identification. It is important to point out that we did not attempt to interpret the sensitivity values and trends with increasing (decreasing) parameter values shown in Table 1 since the main goal was to differentiate between identifiable and not identifiable parameters.

We also studied the sensitivity of the group velocity around other base values for moduli, diameter, and thickness. For instance, we computed sensitivities for E_C and E_L in the range [50 kPa, 500 kPa], G_{LC} in the range [20 kPa, 100 kPa], while the diameter and thickness ranges were [2 mm, 9 mm] and [0.5 mm, 1 mm], respectively. All our sensitivity analyses yielded results similar to those reported in Table 1 and led to the same conclusion: the group velocity is much more sensitive to changes in E_L , h, and D than to changes in G_{LC} and E_C . These other results are not shown here for the sake of brevity.

Lastly, we would like to point out that the sensitivity results presented herein should be interpreted carefully. The reason for the lack of sensitivity of group velocity to shear modulus is simply due to the fact that the loading used in our studies produced modes of deformation that were dominated by bending-like behavior (i.e. shear deformation of the cross section was small in comparison). In theory, there exist frequencies high enough as to produce wavelengths of the order of the thickness of the artery that would lead to sensitivity in G_{LC} . However, we used loading signals whose frequency content resembled those used in real experiments and expect that, in practice, our sensitivity results and conclusions would hold over a wide range of combinations of arterial geometries and material properties.

2.1.3. Surrogate Model Formulation—In this section, we describe our approach for constructing surrogate models for arterial vessels immersed in a fluid. To this end, we employ sparse grid polynomial interpolation in order to construct maps that relate input

parameters (e.g. geometric features and material parameters) to our main quantity of interest (i.e. group velocity).

Let $v_n(T, t, \xi)$ be the normal particle velocity along path *T* corresponding to a given set of parameters ξ . We can represent the group velocity abstractly as

$$c_q(\boldsymbol{\xi}) = \mathscr{G}(v_n(\boldsymbol{T}, t, \boldsymbol{\xi})), \quad (10)$$

where \mathcal{G} is a linear functional representing the operations described in Section 2.1.1.

Our main task herein is to devise a way to construct efficient and accurate approximations to $c_g(\boldsymbol{\xi})$. In this work, we will use polynomial interpolation to produce approximations $\hat{c}_g^h(\boldsymbol{\xi})$. A straightforward approach to this problem is to use tensor product representation of univariate polynomials along each parameter dimension. Using tensor products, Eqn. (10) is represented as

$$\hat{c}_a^h(\boldsymbol{\xi}) = \Phi_1(E_L) \otimes \Phi_2(E_C) \otimes \Phi_3(h) \otimes \Phi_4(D) \quad (11)$$

where $\Phi_1(E_L)$, $\Phi_2(E_C)$, $\Phi_3(h)$ and $\Phi_4(D)$ are univariate polynomials. To create a polynomial interpolant using a conventional tensor product representation, the total number of points needed is $N_Q = \prod_{i=1}^4 N_i$, where N_l is the number of points for a particular parameter. We can observe that the total number of points N_Q increases exponentially with the size of the parameter vector. This result is known as the curse of dimensionality as the computational cost of creating the polynomial interpolant also increases exponentially with the size of the parameter vector (Le Maître & Knio 2010).

To circumvent (at least in part) the curse of dimensionality, sparse tensorization is commonly used to create polynomial interpolants. Sparse interpolation grids use far fewer collocation points than those used by a conventional tensor product representation. In fact, sparse grids can reduce the number of collocation points needed for accurate interpolation by several orders of magnitude. This reduction in the number of interpolation or collocation points translates directly into computational savings as each point requires a finite element simulation.

A common approach to construct sparse interpolants is to use the Smolyak's interpolation algorithm (Smolyak 1963). The Smolyak's algorithm provides a methodology to create interpolation functions based on a coarse grid of points in a multidimensional space. The collection of this minimum number of points is called a sparse grid. For example a typical sparse grid in two dimensions is given in Fig. 2(a). Smolyak's algorithm interpolates using the sparse grid by extending univariate interpolation formulas to a multivariate case in a special way. For example, Fig. 2(b) shows interpolation of the function $\exp(-x^2 - y^2)$ using sparse grid and Smolyak's algorithm. Details of the Smolyak's algorithm have been omitted here for the sake of brevity and focus. The reader is referred to references (Le Maître & Knio 2010, Klimke 2006) for more information on general sparse grid interpolation.

We use the Smolyak's algorithm to create sparse grid interpolants of the group velocity with respect to the material moduli and geometric parameters. We describe this sparse interpolant (abstractly) as an operator $\mathcal{A} : \mathbb{R}^4 \mapsto \mathbb{R}$. That is, mathematically we define the group velocity as

$$\hat{c}_{g}^{h} := \mathscr{A}(\boldsymbol{\xi}), \quad (12)$$

where \hat{c}_g^h is the interpolated group velocity obtained via Smolyak's algorithm. Our goal is to use \hat{c}_g^h in lieu of full finite element simulations in our inverse problem.

An error estimate is used for assessing the accuracy of the interpolant. This error estimate is defined with respect to the level of interpolation, which in turn is a function of the number of points in the sparse grid (Chapter 3 in (Klimke 2006)). Let the interpolant created at k^{th} and $k+1^{th}$ levels of interpolation be given by $\hat{c}_g^{h,k}$ and $\hat{c}_g^{h,k+1}$, respectively. We determine a sufficiently accurate interpolant in $\hat{c}_g^{h,k}$ if the following condition is met.

$$\left\|\hat{c}_{g}^{h,\boldsymbol{k+1}} - \hat{c}_{g}^{h,\boldsymbol{k}}\right\|_{\infty} < \varepsilon, \quad (13)$$

where $\|\cdot\|_{\infty}$ refers to the maximum-norm. The parameter ε is a user-defined tolerance. It can be shown that as the level of interpolation increases, the error in interpolation decreases (Chapter 3 in (Klimke 2006)). However, the higher the level of interpolation the more collocation points are needed and, hence, the higher the computational cost of building the interpolant.

2.2. Algorithm for Creating the Surrogate Model

Now, we describe the algorithm for creating a surrogate model using sparse grid interpolation. First, we create a sparse grid where the axes are the components of the parameter vector ξ^i , where *i* is the interpolation level. As mentioned before, the level of interpolation is directly related to number of points in the sparse grid. Let ξ^i_k , $k = 1, ..., N_i$ represent the collocation points at level *i*, where N_i is the total number of points. Each interpolation point, ξ^i_k on the sparse grid represents a four-dimensional vector of moduli and geometric features. Then, for each interpolation point, we perform a finite element simulation to obtain the particle velocity along path *T*. The group velocity is then calculated for each interpolation point using Eqn. (10). The group velocity for the k^{th} point at the *i*th level is given by $c^i_{g,k}$. Once the group velocity has been obtained for all interpolation points, we use Smolyak's algorithm to create an interpolant of the group velocity. We terminate the surrogate creation when the error metric given in Eqn. (13) is met. The steps for the creation

of a surrogate model are given in Algorithm 1.

Algorithm 1

Creation of the group velocity surrogate model.

Requ	uire: $oldsymbol{\xi}_l,oldsymbol{\xi}_u\in\mathbb{R}^4$	▷ Upper and lower bounds.
Requ	uire: ε	\triangleright Error threshold.

12:	i = i + 1	
13:	end while	

2.3. Inverse Problem Formulation

Let c_g^m denote the group velocity measured in an experiment. Then, the elastic moduli and geometry are reconstructed by solving

$$\hat{\boldsymbol{\xi}} = \underset{\boldsymbol{\xi} \in [\boldsymbol{\xi}_l, \boldsymbol{\xi}_u]}{\operatorname{argmin}} \| \hat{c}_g^h(\boldsymbol{\xi}) - c_g^m \|^2, \quad (14)$$

where ξ_i and ξ_u are the lower and upper bounds of ξ , respectively, and ξ is an optimal value of ξ .

3. Numerical Results

In this section, we investigate the performance of the proposed sparse grid interpolation approach using numerical experiments with simulated data. To this end, we first constructed a 3D finite element model of an artery immersed in water. A Sommerfeld condition was used to model non-reflecting boundaries in both the artery and surrounding fluid. The density of both water and artery was taken as 1000 kg/m^3 . The artery was excited using a half sine pulse load with a duration of $406 \mu s$. Continuum 8-node hexahedral elements were used in all simulations and convergence studies were carried out to determine a suitable mesh for our computations. That is, we refined finite element meshes until the group velocity did not change beyond a specified tolerance. Transient analyses were carried out

using 85 time steps of 40 μ s for a total time of 3.4 ms. All finite element simulations were performed using SIERRA/SDA from Sandia National Laboratories.

3.1. Construction of the surrogate model

A group velocity surrogate model was created using Algorithm 1. For this purpose, we used the spinterp toolbox in MATLAB[®] as described in (Klimke & Wohlmuth 2005). The circumferential (E_C) and longitudinal (E_L) moduli were sampled from the range [60, 400] kPa, the thickness was sampled from the range [0.3, 1] mm and the diameter from the range [2, 7] mm. We used $\varepsilon = 10^{-5}$ as the stopping interpolation error as per Algorithm 1. Using this error tolerance, the total number of interpolation points (i.e. finite element simulations) used to create the surrogate was 505.

To verify the accuracy of the surrogate model, we generated a test data set comprised of 25 random parameter vectors $\boldsymbol{\xi}$ sampled from the given moduli and geometry domains. For each parameter vector in the test set, we obtained a group velocity c_{g} from 3D FE

simulations and the group velocity c_g^h from the surrogate model. We evaluated the error in the group velocity prediction as

$$e_{cg} = \frac{\left|\overline{c}_g - \hat{c}_g^h\right|}{\overline{c}_g} \times 100 \quad (15)$$

The average e_{cg} using the test data set was 8.47% and the maximum was 18.51%. It is important to keep in mind that this error does not translate into a commensurate error in the solution of the inverse problem (14) when a surrogate model is used. In fact, an effective surrogate model is one that preserves the topology of the objective function in the optimization problem such that the correct minimum is found despite the presence of errors in magnitude.

3.2. Inverse problem solution using simulated data

Simulated data was generated using the high fidelity 3D finite element model for different combinations of moduli and geometry as shown in Table 2. We first performed inversions for cases in which the data was not corrupted with noise, and then for cases in which Gaussian noise was added to the computed particle velocity before computing the group velocity. The corrupted data was generated as

$$\hat{v}_n(\boldsymbol{T}_i, t) = v_n(\boldsymbol{T}_i, t)(1 + \gamma \eta(\boldsymbol{T}_i, t))$$
 (16)

where $v_n(\mathbf{T}_i, t)$ is the corrupted normal particle velocity, γ represents the noise level and $\eta(\mathbf{T}_i, t) \sim \mathcal{N}(0, 1)$ is a random variable drawn from a standard Normal distribution (independent for each time and position).

We solved the inverse problem in Eqn. (14) using the Optimization Toolbox in Matlab. Due to the computationally inexpensive nature of the surrogate model, we were able to use a global search algorithm (fminbnd in MATLAB). The results of the inversion without noise

are reported in Table 2. It can be seen that the longitudinal modulus E_L , diameter D, and thickness h were identified with reasonable accuracy. However, the circumferential modulus E_C was not identified correctly. This latter result is in agreement with the fact that the group velocity displayed little sensitivity to E_C in our numerical studies. Table 2 also shows the group velocity predicted by the surrogate model at the identified parameters and the corresponding group velocity (actual) computed from 3D FE simulations. It can be seen that the group velocity values predicted by the surrogate are very close to those computed from the high fidelity simulations.

Table 3 shows the results of inversions performed on data polluted with Gaussian noise. It can be seen that as the noise level increases, the percentage error in prediction of the materials properties and dimension also increases, as expected. However, the errors remain relatively low for all parameters, except for E_C as noticed previously.

4. Experimental Results

In this section, we study the performance of the proposed methodology using laboratory experiments. To this end, we conducted two separate experiments; one using a rubber tube and another using a porcine carotid artery immersed in saline solution subjected to different internal pressures. The proposed algorithm was used to reconstruct geometric and material properties from measured group velocity.

4.1. Description of the Experiments

A schematic of the experimental setup for the porcine carotid artery is shown in Fig. 3. The artery was immersed in a saline solution and its ends were fixed. A linear array transducer was used to apply an ultrasonic pulse excitation in the middle section of the artery and to measure the normal particle velocity along the top surface (see Fig. 1). The force duration was 406 μ s. We report results for four different internal pressures: 20, 40, 60 and 80 mmHg.

For the rubber tube experiment, we used the same setup as was used for the artery. The rubber tube was subjected to an internal pressure of 10 mmHg. At this pressure, the thickness of the tube was measured at 0.94 mm and the outer diameter was 6.5 mm. The data for the artery experiment was recorded with a sampling frequency of 7.5 kHz. The spatial sampling was performed with a spacing of 0.154 mm. For the rubber tubes, the sampling frequency was 5.68 kHz, and the spacing between two consecutive measurements was also 0.154 mm. The shear moduli of the rubber material in the tube was measured in a separate shear wave experiment and was estimated to be G = 93 kPa. Assuming incompressibility, the Young's modulus for the rubber tube was calculated as E = 279 kPa (i.e. $3 \times G$).

4.2. Inverse Identification Results

We processed all the experimental data using the same surrogate model and optimization procedure presented in Section 3. We first present the results obtained for the rubber tube. The value of group velocity obtained from the measured particle velocity was 6.98 m/s. Using our inverse problem framework, we estimated the geometric and material properties of the tube to be $E_L = 230 \ kPa$, $E_C = 90 \ kPa$, $D = 6.7 \ mm$, and $h = 0.96 \ mm$. Since the tube

was isotropic, we expected that the values of E_C and E_L would be similar, which was not the case. This is a reflection of the lack of sensitivity of the group velocity with respect to E_C . Using the formula in Eqn. (15), we estimated the respective errors to be 17%, 67%, 3% and 2%. Furthermore, we performed a 3D FE simulation (with the estimated parameters) and determined the group velocity to be 6.54 m/s, which corresponds to a relative error of 6.3% with respect to the experimentally measured value. We can see that, with the exception of E_C , all parameters were estimated with good accuracy.

We also compared dispersion curves obtained from the 3D FE simulations corresponding to the identified parameters with the dispersion curves obtained from the experimental data. To get the dispersion curves, we performed a two-dimensional (2D) fast Fourier transform (FFT) of the normal particle velocity along the measurement path on the artery (see Section 2.1.1). We used the procedure described in (Bernal et al. 2011) to obtain the dispersion curves from the 2D FFT. After taking the 2D FFT, the peaks in the magnitude spectrum are identified at each frequency in the analysis bandwidth. The coordinates of the peaks (*f*, *k*) can be used to calculate the phase velocities for different modes through $c = 2\pi f/k$. Typically, before peak identification is performed, a magnitude threshold is applied to the Fourier spectrum. The latter step eliminates spurious, low-magnitude phase velocities and the most dominant modes are emphasized. In this study, we used a threshold of 0.10 (i.e. mode amplitudes less than 0.10 of the peak value were masked).

Figure 4 shows a comparison of the experimental and simulation dispersion curves for the rubber tube. The results are given for the frequency range [100, 1000] Hz. The highest frequency was selected based on the smallest wavelength that could be adequately captured with the 3D FE mesh (using about 10 elements per wavelength). The lower frequency bound was selected such that at least one wavelength was captured along the measurement path. We can observe that the dominant modes, shown in bold, obtained from the experimental data and optimized material properties are close to each other over the range [600, 900] Hz. The dominant modes are those for which the 2D FFT produced the largest amplitudes.

We can also observe close agreement between computed and experimentally measured secondary, high order modes (shown with solid and dashed lines in Figure 4) for phase velocities below 5 m/s. However, we observed that the FE simulation produced a mode above 700 Hz with phase velocities between 10 and 25 m/s that was not present in the experimental data. This type of discrepancy can be attributed to some of the assumptions made in our models. For instance, no damping was included in the FE model, while silicon rubber is to some extent viscoelastic and high order modes are naturally attenuated. On the other hand, these high order modes would be present in the undamped FE simulations. The latter can partially explain why the dominant mode obtained from the experimental data spans over a wider frequency range than that of the computed dominant mode. Another important point to consider is that the group velocity depends on the phase content of the group. It is expected that there would be some discrepancy between the frequency content of the excitation signal used in experiment and that used in the FE simulations.

Next we consider the inverse identification of material properties and dimensions for the excised artery. The results are summarized in Table 4, which shows that the recovered

diameter and thickness closely approximate the measured values. We can observe from this table that the maximum relative error was 11.59% and occurred for the diameter estimate in the 80 mmHg case.

The recovered material properties and group velocities are presented in Table 5. The predicted or identified group velocities (\hat{c}_g) were obtained from 3D FE simulations using the identified material and geometric properties. Table 5 shows that the predicted group velocities are very close to the group velocities (c_g) obtained from the experimental data. As for the prediction of material properties, the values obtained for E_L were consistent with those reported in (Bernal et al. 2011). However, the E_C values obtained seem to be inaccurate, which is consistent with the findings of our sensitivity studies.

Figure 5 compares the dispersion curves obtained from the experimental data and those obtained from 3D FE simulations using the recovered moduli and geometry. As in the silicon tube experiment, close agreement is observed between the dominant modes of the data and those of the FE simulations, for arteries at 20, 40 and 60 mmHg hydrostatic pressures. The discrepancy in the dispersion curves for the 80 mmHg case was larger than for the other cases. However, the identified diameter and thickness were estimated with sufficient accuracy and the longitudinal modulus followed an expected trend (i.e. value increased with pressure). Nonetheless, we would naturally have less confidence in the results for the latter case due to the higher error in the dispersion curves. Lastly, we would like to point out that some of the discrepancies observed in the dispersion diagrams can be attributed to some of the assumptions made in the FE simulations as previously discussed.

5. Concluding Remarks and Future Work

The prediction of thickness, diameter, and material properties are of paramount importance in the characterization of cardiovascular diseases. In this work, we presented a novel approach for the fast and noninvasive identification of material properties and geometry of arteries excited by an ultrasonic pulse. The main algorithm used a Smolyak's sparse grid collocation technique to create a surrogate model mapping the moduli and dimensions to the group velocity. Once a surrogate model is created, the identification process can be carried out in near real time across different specimens and internal pressures. The main advantage of the proposed approach is that the surrogate model combines computational speed with knowledge of the fundamental physics of the underlying wave propagation problem.

We applied the proposed inversion methodology to obtain longitudinal and circumferential moduli as well as thickness and diameter in an excised artery subjected to different internal pressures and a silicon tube. It was found that the proposed method could effectively identify the longitudinal modulus, diameter and thickness. However, the circumferential modulus could not be identified. The inaccuracy in the identification of E_C can be attributed to the fact that the group velocity measured along a longitudinal path seems to be relatively insensitive to changes in this parameter. It seems plausible that devising experiments that capture wave motion in the circumferential direction would yield more accurate reconstructions of E_C ; a direction that would be pursued in the near future.

To apply the current methodology *in vivo*, the high fidelity and surrogate models have to incorporate surrounding tissue and viscoelastic effects (both in the artery and the surrounding tissue). Furthermore, the viscosity of blood may have to be included. These features can be naturally incorporated in the proposed sparse grid collocation framework. However, these model extensions are expected to increase the dimensionality of the problem, and hence the computational cost of constructing the surrogate model. Yet, this increase in computational cost can be mitigated by the used of sparse grids. Furthermore, due to their uncoupled nature in collocation approaches, high-fidelity simulations can be carried out straightforwardly in parallel. Moreover, surrogate models are built offline and can be used across many different inversion cases in near real-time, compensating for the initial high-computational cost.

Another direction that will be pursued in future research is the development of adaptive strategies for constructing the surrogate model. The basic premise would be to start with a coarse grid of parameters (e.g. geometry and material) and choose collocation points according to the sensitivity of a quantity of interest along different coordinates (i.e. parameters). Similar approaches have been successfully used for uncertainty quantification (Ganapathysubramanian & Zabaras 2007).

Lastly, we would like to emphasize that what level of model complexity, and hence accuracy, is the most adequate for diagnostic purposes remains an open issue that we intend to investigate in the near future. For instance, we will study the use of material models that include variable fiber orientation. Furthermore, we will investigate the diagnostic value of parameters obtained from proper linearization of nonlinear constitutive models, which would be more consistent with arterial mechanics than the simpler Hookean models used herein.

Acknowledgments

This research was supported in part by grants EB02167 and EB02640 from The National Institute of Biomedical Imaging and Bioengineering (NIBIB). The authors thank Sandia National Laboratories for allowing the use of SIERRA/SDA for this work.
