Introduction The functioning of modern urological departments and the high level of service they provide is possible through, among other things, the use of modern laser techniques.

Material and methods Open operations have been replaced by minimally invasive procedures, and classical surgical tools by advanced lasers.

The search for new applications with lasers began as technology developed. Among many devices available, holmium, diode and thulium lasers are currently the most popular.

Results Depending on the wavelength, the absorption by water and hemoglobin and the depth of penetration, lasers can be used for coagulation, vaporization and enucleation. In many centres, after all the possibilities of pharmacological treatment have been exhausted, lasers are used as the primary treatment for patients with benign prostatic hyperplasia, with therapeutic results that are better than those obtained through open or endoscopic operations. The use of lasers in the treatment of urolithiasis, urinary strictures and bladder tumours has made treatment of older patients with multiple comorbidities safe, without further necessity to modify the anticoagulant drug treatment. Laser procedures are additionally less invasive, reduce hospitalization time and enable a shorter bladder catheterization time, sometimes even eliminating the need for bladder catheterization completely. Such procedures are also characterized by more stable outcomes and a lower number of reoperations.

Conclusions There are also indications that with the increased competition among laser manufacturers, decreased purchase and maintenance costs, and increased operational safety, laser equipment will become mandatory and indispensable asset in all urology wards.

Key Words: urology <> lasers <> bladder outlet obstruction

INTRODUCTION

In the last two decades laser techniques have become an increasingly popular method of treatment for patients with benign prostatic hyperplasia, bladder tumours, urolithiasis, urinary tract strictures or lesions of the external genitalia. The first reported use of laser technique in urology was published by Stethler in 1976 [1]. Some of initially introduced laser procedures had to be modified or abolished because of numerous postoperative complications, the need for prolonged catheter maintenance and because of unpredictable therapeutic effects. Nowadays due to equipment advancement, better understanding of urologists' needs on the part of producers, and

growing experience of the operators laser treatments are a favourable alternative to traditional surgical procedures. Increasing accessibility to the appropriate equipment, relatively short learning curve and promising therapeutic effects has caused a growing interest in these methods. The results of longer than average survival time are seen in older patients with coexisting cardiac disorders requiring anticoagulant prevention. For those patients laser technique is frequently much safer treatment than classic operation. There are a lot of advantages of laser procedures over traditional surgeries. First, there is a greater precision and accuracy. Secondly lasers procedures are less invasive, lasers energy heat-seals blood vessels and in result there is less bleeding, swelling, pain,

or scarring. Third, laser procedures are good alternative for patients with high comorbidity who are not suitable for open operations. Furthermore laser operating and hospitalization time may be shorter, more procedures may be done in outpatient settings. On the other hand some disadvantages of laser operations should be also taken into account. First of all not many doctors are trained to use lasers. Additionally laser equipment is expensive and unwieldy and it should also be remembered that strict safety precautions must be followed in the operating room when lasers are used.

Laser, which name comes from the first letters of the words in a phrase "Light Amplification by Stimulated Emission of Radiation", is a tool that emits monochromatic light. The light source may include gas, crystal, semiconductor or dye.

The interaction between the laser beam and the tissue depends on physical phenomena, such as reflection, dispersion and absorption. Some part of laser radiation is reflected, therefore useless for surgical purposes. Additionally, reflected light can cause unintended thermal damage to surrounding areas. From a medical perspective, the most important phenomenon is the absorption of the laser light by chromophore, on which the light is converted into thermal energy. The light in tissues is absorbed by haemoglobin, water or melanin. Depending on the temperature the tissue is heated, hence undergoes coagulation or vaporization. In case of a low tissue absorption coefficient the laser beam penetrates deeper, whereas a high absorption coefficient results in shallow penetration. The effect, however, is not only medium-dependent. The wavelength of the laser also plays an important role. For lasers emitting shorter wavelengths, a greater amount of energy is converted into heat [2].

Laser lithotripsy generally involves two basic mechanisms, photomechanical and photothermal. Photothermal lithotripsy produces small fragments and is effective in all stone compositions, whereas photomechanical lithotripsy produces larger fragments and is not effective in calcium oxalate monohydrate and cysteine stones. Photomechanical laser lithotripsy occurs because of the production of transient stress waves from the deposition of laser energy. An example of photomechanical mechanism is formation of cavitation bubble. It occurs when pulsing types of lasers are used. A cavitation bubble is caused by rapid expansion of water vapour at the laser fiber tip. The bubble then rapidly collapses releasing very strong pressure waves which causes stone fragmentation [3]. Another photomechanical mechanism is production of plasma on the fiber tip. It occurs with extremely short pulse duration (<500 ns). Due

to plasma instability, its fast expansion and contraction produce pressure waves that can disrupt stone [4]. Photothermal lithotripsy may occur either by direct absorption of protons and thermal stone disruption or by water within the stone rapidly heating and causing fast vapour flow that disrupts the stone [5].

Lasers types

Currently, the most commonly used lasers in urology are KTP:YAG (Potassium titanyl phosphate), LBO:YAG (lithium borate), diode lasers, Holmium (Ho):YAG and Thulium (Tm):YAG lasers. In the past many other types were used, however, due to a large number of complications, their use was discontinued [2, 6, 7].

Characteristics of particular individual lasers

The Nd:YAG laser was the most commonly used laser in the past and therefore is the most studied one. It is characterized by more than 1 cm tissue penetration and by 1064 nm wavelength. It causes deep coagulative necrosis and considerable thermal tissue injury. Nd:YAG laser can be used for non-contact 'visual laser ablation of the prostate' (VLAP), contact ablation or interstitial laser coagulation (ILC) of the prostate. Oedema occurring after procedure frequently leads to irritative lower urinary tract syndrome (LUTS) and urinary retention, which often requires long-time catheterization.

Ho:YAG laser is a pulsed type of laser that emits energy absorbed by the water. It is characterized by wavelength of 2140 nm and pulse duration of 350 ms. The depth of penetration in the prostate tissue is only 0.4 mm. Therefore the depth of necrosis and thermal damages is limited. Ho-laser causes rapid coagulation of small and medium-sized vessels to the depth of about 2 mm. Because this laser requires contact with the tissue, prostate can be precisely incised, dissected and enucleated. Ho-laser is mainly used for procedures on the prostate, in lithotripsy, ablation of urothelial tumours and for upper and lower urinary tract strictures incision [8].

KTP: YAG laser, also called green light laser, is derived from Nd: YAG laser. Passing the invisible Nd:YAG beam *via* a KTP crystal, doubles the frequency and halves the wavelength from 1064 nm to 532 nm. Its energy is selectively absorbed by haemoglobin, but not by water. The penetration depth is about 0.8 mm. It is characterized by a very good coagulation effect, which results in a good control of haemostasis. Because energy of KTP laser is absorbed only by haemoglobin, it is possible to perform operations in noncontact use called photoselective

vaporization of tissue. Due to shallow absorption rate, necrosis of the tissue localized beneath the vaporized area is limited. An additional advantage is an almost bloodless course of the procedure.

The Tm:YAG laser produces continuous, 2000 nm wave. As in Ho-laser, energy is absorbed only by water and slightly shorter wavelength of thulium laser decreases the depth of penetration to 0.25 mm. The Tm-laser is used for transurethral vaporization, enucleation or resection of the prostate.

The lithium triborate (LBO) laser is derived from KTP-laser. The wavelength of both lasers is equal. However, LBO-laser has an accelerated and a more efficient energy transfer and enhanced working distance (from 0.5 mm for KTP to 3 mm for LBO) [9]. A significant disadvantage of this laser is a marked decrease in haemostatic ability in comparison to KTP laser [10].

Diode lasers have been available for long time, yet, their clinical application has been limited. Diode lasers emit a beam of wavelength between 940 to 1470 nm. Their energy is absorbed by both water and haemoglobin. As a result, good haemostatic and vaporisative effects are obtained [2]. Data regarding the penetration depth of diode lasers differs considerably between particular reports. Some reports on a 980 nm diode laser demonstrate its better haemostatic effect during prostate vaporization in comparison to 120 W LBO laser, however, higher incidence of complications, such as postoperative irritative symptoms and epididymitis, is noted [11].

Laser applications in treatment of patients with bladder outlet obstruction

Moderate-to-severe lower urinary tract symptoms in patients with benign prostatic hyperplasia (BPH) appear in about one quarter of men in their 50s, one third of men in their 60s, and about half of all men in the eight decade of life [12].

Surgical procedures used in these patients include classical methods, such as TURP (transurethral resection of the prostate) and adenectomy, as well as lasers techniques. In the United States laser techniques treatments are used in approximately 60% of patients with BPH or BPO (benign prostatic obstruction) after all the possibilities of pharmacological treatment have been exhausted [13, 14]. The use of different lasers types allows the performance of BPH/BPO ablation, enucleation, coagulation and vaporization. Mortality, necessity of reoperation, requirement of blood transfusion after surgery, as well as the number of water poisonings, is dependent on the volume of the removed prostatic gland and the duration of the procedure. The number of com-

plications increases significantly in cases in which prostate is greater than 60 ml and when the operation time exceeds one hour. The need for reoperation after TURP and adenectomy during 8 years of follow-up observation (re-TURP, bladder neck incision, urethrotomy) is 14.7 and 9.8% respectively [15]. Perioperative complications after laser prostate treatments occur in approximately 20% of patients, however, 80% of these complications are considered low-grade (Clavien grade I-II) [16]. In addition, laser treatments are performed in 0.9% NaCl environment, so transurethral resection syndrome, which occurs in 1.4% pts. after TURP, does not occur after laser techniques [15, 17].

For patients who have been qualified for the surgery (TURP/open procedure) with underlying cardiac and neurological diseases and receive oral anticoagulants the standard procedure is withdrawal of anticoagulant therapy 5-7 days prior to the procedure and administration of low molecular weight heparin injections. This treatment is commonly maintained for a period of seven days after surgery. The use of heparin protects from vein thrombosis incidents, however, there is an increased risk of intra- and postoperative bleeding. Patients after percutaneous coronary intervention with stent implantation are particularly vulnerable to thrombotic events and those who received metal stents should continuously receive dual antiplatelet therapy (aspirin + clopidogrel) for 4 weeks after surgical interventions. In cases of drug-eluting stents, therapy should last the minimum of 6 months [18].

In randomized study, which compared KTP laser PVP (Photo-Selective Vaporization of the Prostate) and TURP, operation time, especially among less experienced operators and when adenomas were larger than 80ml, was 30-50 min longer in the laser group [19]. When LBO laser (120W) was used the difference decreased to 9 min [19, 20]. Longer time of laser procedure is compensated by lower amount of blood loss (0.45 g/dl vs. 1.46 g/dl) [21]. In a study comparing LBO laser PVP with TURP, blood transfusion was not required in most cases after laser procedures. When comparing blood loss after laser operation and after classic adenectomy the difference is even more evident. An average 8.1% of patients after TURP, and even 13.3% after adenectomy, require red blood cells transfusion [20, 22, 23]. Other randomised trial, which compared PVP with Green-Light120-W laser and TURP in prostates smaller than 80 cc, has been recently published. The authors claim that postoperative functional improvements were durable and equivalent in the two groups. Both techniques had a similar complication rate, however, hospital stay after laser procedure was significantly

shorter [24]. Early outcomes of new 180-W XPS GreenLight laser system have been recently reported. They reveal that photoselective vaporization of the prostate (PVP) seems to be a safe and effective procedure and could play an important role in the surgical treatment of symptomatic BHP patients with larger prostate volumes [25, 26, 27]. In the study that compared holmium laser transurethral incision of the prostate and green light photoselective vaporization of the prostate it has been shown that both methods seem to be equally effective, safe and durable surgical treatment options for small prostates even in high risk patients [28].

An alternative method is vaporization with diode lasers, however, usage of these lasers must be carefully considered due to the numerous postoperative complications, such as bladder neck stenosis, the need for reoperation, formation of stones, strictures of the urethra or the occurrence of stress urinary incontinence [11, 29]. In the study comparing diode laser with TURP authors have shown that diode laser vaporization (980 nm) offers a safe and feasible procedure in the management of patients with symptomatic benign prostatic hypertrophy, however, at longer follow-up the functional outcome of diode laser vaporization has been less efficient than TURP [30]. Other study comparing vaporization of the prostate with green light laser and diode laser presented no significant difference between improvement of voiding and micturition parameters. However, a significantly higher reoperation rate was observed in the diode group due to obstructive necrotic tissue, bladder neck and persisting or recurrent adenoma. Careful clinical application of diode laser type is warranted by authors [29].

Next device used in patients with narrowing of bladder neck/BPH is holmium laser. Possible procedures include ablation (HoLAP), enucleation (HoLEP) and resection (HoLRP) of prostate. Laser with power of 60W, 80W and 100W are currently in use. In case of procedures performed with 60W, 80W lasers treatment results are comparable with those obtained after TURP [31, 32]. HoLRP should be performed only when the gland is small or medium sized [33]. Available meta-analyses indicate that although HoLRP is a surgical technique that requires longer operations time (17.7-31.0 *versus* 43.4-57.8 h), the time of hospitalization after the procedure is shorter (27.6-59.0 *versus* 48.3-85.5 d) [34]. Long-term observations have shown that in patients who underwent treatment for prostate of volume more than 100 ml outcomes and the necessity of reoperation are at a similar level as after adenomectomy [35]. Recent study comparing HoLEP with TURP, showed slightly better postoperative results in during 12-month fol-

low-up in HoLEP group, as well as significantly better perioperative results and similarly low complication rates. However, the operative time and the incidence of postoperative dysuria favoured TURP [36].

Vaporisation (ThuVAP), vaporesction (ThuVARP), vapoenucleation (ThuVEP) and enucleation of the prostate (ThuLEP) with thulium laser are also effective and promising techniques. The results of a randomized study, which compared ThuVEP and HoLRP, indicated that during the 3 month follow-up observation both methods yield comparable improvement in urodynamic parameters, and in the case of ThuVEP, lower blood loss during surgery was observed [37]. During vapoenucleation of big prostates (average volume adenoma – 108,6 mL) 86% reduction in prostate volume assessed by TRUS was achieved and a 88% decrease in PSA levels was observed [38]. Recent trial showed that thulium laser resection of the prostate is safe, feasible, and efficient alternative to TURP for treating patients with BPH BPH demonstrating reliable perioperative safety, fewer complications, comparable efficacy, but longer operative time [39]. However, thulium lasers do not allow lithotripsy which limits their application and usefulness. Complications profile after laser treatments is more favourable than after classic procedures. TURP syndrome was not observed after laser procedures and only few cases of prostate capsule perforation were reported [20, 22, 23]. The incidence of urinary incontinence after KTP PVP is 1.4%, 0.7% after LBO PVP, after diode PVP ranges from 0-10%, and after HoLEP is about 0% while after TURP is 3% [40-44]. Retrograde ejaculation occurs at a similar level in laser and TURP groups and is observed in approximately 50% of cases. Narrowing of the bladder neck was observed in 3.6% of patients after LBO PVP and in 7.4% of patients after TURP [20, 22]. In a recent large analysis of complications after classic TURP and laser transurethral resection of the prostate (L-TURP) demonstrated a modest benefit for L-TURP compared to TURP patients. Overall complication rates, haematuria and necessity of blood transfusion were comparable, however, infections were significantly more frequent in TURP group [45]. In other recent study, which compared intraoperative, early, and late postoperative complications after procedures in which various laser devices were used, it was shown that with the exception of re-catheterization, no significant difference in the rate of complications was observed. Recatheterization was the most frequent complication when diode laser was used [46]. A case of massive irrigant fluid leakage into the retroperitoneal space leading to intestinal paralysis and intra-abdominal hypertension after holmium laser enucleation of the prostate has been recently published [47].

Laser applications in treatment of patients with urolithiasis

Modern laser techniques are an indispensable tool for treating patients with urolithiasis [48]. The advancement of the new generation ureteroscopes and the increasing power of the lasers allow lithotripsy of larger concretions to be shorter. Over 90% of lithotripsy procedures are successful [49]. The effectiveness and safety of laser lithotripsy has been proven in multiple studies regarding symptomatic ureteral stones in every location, treatment of pregnant women, overweight/obese patient and children of all ages [50, 51, 52].

It was shown in the literature that the Ho:YAG laser is a suitable tool to disintegrate ureteral calculi irrespectively of its location [53]. This type of laser is also adequate tool for laser lithotripsy of ureteral post-SWL (shock wave lithotripsy) stones [54]. For some cases with multiple intrarenal calculi, ureteroscopy with Ho:YAG laser lithotripsy can be an alternative to ESWL or PNL, with acceptable efficacy and low morbidity [48]. It has been proven that both laser lithotripsy and pneumatic lithotripsy are equally safe and efficient for stone fragmentation, thus laser lithotripsy is associated with lower stone migration rate and easier retrieval of stone fragments [3]. It is also shown that laser lithotripsy is a superior method in cost-effectiveness analysis comparing to SWL for renal stones <1.5 cm [55].

Endopyelotomy may be also performed using a laser. It is comparably efficient and as safe as open pyeloplasty procedures however, some limitations should be noted. The facts that stricture shouldn't be longer than 2 cm and the operated kidney should be free of stones should be taken into consideration during qualification for treatment. The incision should be made laterally, so as not to damage possible crossing vessels [49, 56].

Laser applications in treatment of patients with bladder cancer and strictures of the urinary tract

Laser techniques have also found their place in the treatment of patients with tumours of the urinary bladder. First attempts to use laser in bladder cancer (BC) therapy were published by Staehler and Hofstetter in 1979 [57]. However, first large report on laser use in BC therapy was published by Beer in 1989 [58]. Despite promising outcomes, this method was abandoned for years. The reason for that might be possible bowel injury while using deep penetrating Nd:YAG laser [59]. Nowadays with introduction of new devices, laser resection techniques for blad-

der tumor are coming back [60, 61]. Several reports suggest the superiority of the laser method over TURBT, because it seems that a recurrence of cancer after laser treatments is not more frequent than after TURBT and complication rates seem to be lower after modern laser procedures when compared to TURBT [49, 62]. In available studies regarding BC laser resections only 7 complications in total were mentioned [62]. Neither deaths, nor acute bleeding has been mentioned in any of the reports. Unfortunately, in available literature most studies are non-randomized. In addition, there are no studies that compare different methods.

Laser techniques allow laser vaporization (LV), en bloc resection of BC and BC ablation. LV is suitable as an outpatient procedure because it does not require general anaesthesia. In some reports LV was performed only with topical lidocaine yielding a good effect [63]. However, staging of BC is impossible after LV, therefore, LV is not recommended for the treatment of primary BC. BC en bloc resection is a method that in contrast to LV may provide oncological radicality. It consists of superficial circular incision around the tumor keeping in a distance of approximately 2–5 mm from tumour. With the aid of this marking line, the tumor is afterwards extracted by blunt dissection. The correct depth is reached when striated fibres of detrusor muscle are seen [64]. Laser operations of BC seem to be an interesting alternative to classic TURBs, but still their potential needs to be proven in larger prospective randomized controlled studies with long-term follow-up. Future expectations will show whether en bloc resection of BC are preferable over the traditional "incise and scatter" resection technique which is contrary to all accepted oncological surgical principles [59]. BC ablation is also an option especially in low-grade non-muscle invasive bladder cancers (NMIBC) in elderly patients. The procedure seems to be effective, well-tolerated, associated with a low risk of complications and can be successfully delivered in an outpatient setting [65, 66]. In addition, hexylaminolevulinat (HAL) photodynamic diagnosis (PDD)-assisted TURBT is also worth mentioning. This fluorescence using method helps to reveal lesions that may not be seen with standard white light cystoscopy. However, despite offering a more accurate diagnostic assessment of a bladder tumour, HAL-PPDD does not lead to lower recurrence rates of newly presenting NMIBC compared with the best current standard of care [67, 68].

Urethral strictures, even though optical or blind urethrotomy remains the gold standard procedures, can be also operated with laser technology. Endourethrotomy with laser is minimally invasive, and

has similar or even superior effectiveness and safety compared with conventional methods [69, 70, 71]. Laser endourethrotomy is also proven to be shorter procedure than conventional methods [72]. The Ho:YAG laser offers a significant advantage with its coagulation ability. Laser efficiently removes scarred tissues by vaporization with minimal thermal damage to adjacent tissues [73]. In long strictures (>1.5 cm) results of laser endourethrotomy are worse, however, therapeutically effective [49, 74]. Although the role of laser urethrotomy in strictures management is not yet defined, may be a good alternative to urethroplasty especially in patients with

high comorbidity who are not suitable for open operations.

CONCLUSIONS

Laser techniques are versatile tools in urology. Particularly significant is their use in patients with diseases of the prostate. Promising therapeutic effects of laser procedures tend to demonstrate their usage in treatment of patients with other diseases.
