UNC-16 (JIP3) Acts Through Synapse-Assembly Proteins to Inhibit the Active Transport of Cell Soma Organelles to *Caenorhabditis elegans* Motor Neuron Axons

Stacey L. Edwards, Logan M. Morrison, Rosalina M. Yorks, Christopher M. Hoover, Soorajnath Boominathan, and Kenneth G. Miller[1]

Genetic Models of Disease Laboratory, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma 73104

ABSTRACT The conserved protein UNC-16 (JIP3) inhibits the active transport of some cell soma organelles, such as lysosomes, early endosomes, and Golgi, to the synaptic region of axons. However, little is known about UNC-16's organelle transport regulatory function, which is distinct from its Kinesin-1 adaptor function. We used an *unc-16* suppressor screen in *Caenorhabditis elegans* to discover that UNC-16 acts through CDK-5 (Cdk5) and two conserved synapse assembly proteins: SAD-1 (SAD-A Kinase), and SYD-2 (Liprin-α). Genetic analysis of all combinations of double and triple mutants in *unc-16(+)* and *unc-16(−)* backgrounds showed that the three proteins (CDK-5, SAD-1, and SYD-2) are all part of the same organelle transport regulatory system, which we named the CSS system based on its founder proteins. Further genetic analysis revealed roles for SYD-1 (another synapse assembly protein) and STRADα (a SAD-1-interacting protein) in the CSS system. In an *unc-16(−)* background, loss of the CSS system improved the sluggish locomotion of *unc-16* mutants, inhibited axonal lysosome accumulation, and led to the dynein-dependent accumulation of lysosomes in dendrites. Time-lapse imaging of lysosomes in CSS system mutants in *unc-16(+)* and *unc-16(−)* backgrounds revealed active transport defects consistent with the steady-state distributions of lysosomes. UNC-16 also uses the CSS system to regulate the distribution of early endosomes in neurons and, to a lesser extent, Golgi. The data reveal a new and unprecedented role for synapse assembly proteins, acting as part of the newly defined CSS system, in mediating UNC-16's organelle transport regulatory function.

KEYWORDS *Caenorhabditis elegans*; axonal transport; JIP3; Cdk5; Liprin; SAD-A; dynein

NEURONS have a unique architecture consisting of a cell soma, one or more dendrites that receive information, and a single axon, which can be a single process or intricately branched. Part of the axon is specialized to form synapses, which integrate and transmit information to other neurons or muscle cells via synaptic vesicles and dense core vesicles. This unique architecture and cell biology places extraordinary demands on the membrane-trafficking and transport machinery. In addition to transporting synaptic vesicles and dense core vesicles long distances into axons, motor neurons must also restrict, or even prevent, the flow of some organelles, including Golgi, lysosomes, and endosomes, into the synaptic region of their axons, which, under normal conditions, are relatively devoid of these organelles compared to cell somas. However, there may be special conditions, such as the need for axon repair or growth, where neurons require cell soma organelles in their axons, so the regulatory system for organelle transport must include components that inhibit, as well as promote, axonal transport. The association of mutations in the axonal transport machinery with neurodegenerative disorders in mice and humans underscores the importance of a properly functioning transport system for the long-term viability of neurons (Holzbaur 2004; El-Kadi *et al.* 2007; De Vos *et al.* 2008; Millecamps and Julien 2013; Maday *et al.* 2014).

The neuron's axonal transport system consists of a system of microtubule tracks and motor proteins that carry cargos along the tracks, as well as proteins that regulate the system.

Microtubules have an intrinsic plus- and minus-end polarity, and axonal microtubules are oriented with their plus-ends pointing outward toward the synaptic region (Burton and Paige 1981; Heidemann *et al.* 1981; Baas and Lin 2011). Plus-end-directed motors from the large family of kinesins carry synaptic vesicles and organelles outward, while the minus-end-directed motor dynein moves them in the opposite direction (Vale 2003; Holzbaur 2004; Hirokawa *et al.* 2009, 2010). The transport of synaptic vesicles, dense core vesicles, and at least some organelles is bidirectional (Kumar *et al.* 2010; Ou *et al.* 2010; Wong *et al.* 2012; Edwards *et al.* 2013; Hoover *et al.* 2014), suggesting that regulated directional biases determine their steady-state distributions.

Based on its strong interactions with Kinesin-1 in multiple invertebrate and vertebrate species, and its biochemical ability to enhance Kinesin-1 motility, several studies have concluded that UNC-16 (JIP3) functions mainly as an adaptor that connects Kinesin-1 to specific cargos to promote plus-end-directed transport into axons (Bowman *et al.* 2000; Cavalli *et al.* 2005; Sun *et al.* 2011). Indeed, there is genetic evidence in mice that JIP3 can function as an adaptor that promotes the Kinesin-1-mediated transport of TrkB receptors as well as one or more unidentified cargos relevant to axon elongation and neuronal degeneration (Huang *et al.* 2011; Sun *et al.* 2013; Sato *et al.* 2015; Watt *et al.* 2015).

However, in multiple species, both invertebrates and vertebrates, a major neuronal phenotype of mutants lacking UNC-16 (JIP3) is the massive accumulation of cell soma organelles in axons (Bowman *et al.* 2000; Brown *et al.* 2009; Drerup and Nechiporuk 2013; Edwards *et al.* 2013), which is also accompanied by the mislocalization of synaptic vesicle proteins (Byrd *et al.* 2001). There is no evidence that this anti-accumulation function of UNC-16 involves a Kinesin-1 adaptor function or the stimulation of Kinesin-1 activity. Indeed, the massive accumulation of organelles at microtubule plus ends in mutants lacking UNC-16 (JIP3) shows that this function of UNC-16 normally inhibits, rather than promotes, the plus-end-directed transport of those organelles, which include lysosomes, early endosomes, and Golgi (Edwards *et al.* 2013).

An attempt to explain the massive organelle accumulation in UNC-16 (JIP3) mutant axons in terms of a defective UNC-16–Kinesin-1 adaptor function led to the stalled transport model (Bowman *et al.* 2000). This model was based on the fact that fly Sunday Driver (JIP3) mutants die as larvae and thus must be derived from heterozygous mothers. The model posited that a small amount of wild-type JIP3 from the maternal contribution of messenger RNA allows organelles to enter axons, but that transport stalls as the maternal JIP3 supply is depleted (Bowman *et al.* 2000). However, this hypothesis was never tested until *Caenorhabditis elegans* studies proved it likely to be wrong by demonstrating that the axonal organelle accumulation also occurs in *unc-16* homozygous mutants derived from homozygous parents

(Brown *et al.* 2009; Edwards *et al.* 2013). Furthermore, the organelle accumulation in *unc-16* mutants occurs in the absence of Kinesin-1 (Brown *et al.* 2009; Edwards *et al.* 2013). A zebrafish study showed that this organelle transport regulatory function of UNC-16 is conserved in both vertebrates and invertebrates (Drerup and Nechiporuk 2013).

Little is known about this regulatory function of UNC-16. In this study, we used an unbiased forward genetic screen in *C. elegans* to discover a previously unknown system through which UNC-16 acts to inhibit the active transport of organelles to axons. The proteins in this system had not previously been implicated in the active transport of cell soma organelles in neurons. Instead, previous studies have suggested that they have highly specialized roles in synapse assembly/ and stability. In an analysis of this new system, we combined the genetic strengths of *C. elegans* with quantitative imaging techniques and time-lapse imaging of lysosomes in motor neurons of living animals. The data revealed that UNC-16's organelle transport regulatory function is unexpectedly mediated by synapse assembly proteins acting as part of a newly defined organelle transport regulatory system: the CSS system. In an accompanying article in this issue, we show that several CSS system proteins also regulate synaptic vesicle transport, further underscoring the counterintuitive dual roles of some synapse assembly proteins in regulating active transport and synapse assembly/stability (Edwards *et al.* 2015).

Materials and Methods

Worm culture and strains

Worm culture and manipulation essentially followed previously described methods (Brenner 1974; Sulston and Hodgkin 1988; Stiernagle 2006). Briefly, culture media was Nematode Growth Medium Light Only Back-peptone (NGM-LOB; Hoover *et al.* 2014). Prior studies defined the culture plate types "spread plates," "streak plates," and "locomotion plates" (Miller *et al.* 1999; Edwards *et al.* 2008). We produced "24-well plates" by dispensing 2.3 ml NGM-LOB media into wells of 24-well untreated tissue culture plates (Corning 3524), seeding each well 2 days later with 6 µl of OP-50 culture, immediately drying the plates with their lids off for 1 hr 15 min in a 37° room, and keeping the plates at room temperature lid side up for an additional 5 days before wrapping them in plastic wrap in sets of six and storing at 4°. To produce 96-well solid media culture plates, we prepared NGM-LOB media supplemented with three times the normal amount of peptone and 1 g/liter of yeast extract. We used a WellMate Microplate Dispenser (Matrix) to dispense 375 µl of media to each well using standard bore tubing. Water for prewarming and priming the input lines and the molten media were kept in a 73° water bath while dispensing to prevent solidification. After solidification of the wells, we used the WellMate to dispense 10 µl of OP-50 bacteria culture to each well with small-bore

tubing. We then dried the plates with their lids off for 1 hr 15 min in a 37° room before putting their lids back on, repacking and sealing them in their original packaging, and incubating them at 37° for 64 hr. At the end of this time, we unpackaged the plates, removed the condensation from each lid using a Kimwipe, repackaged them, and stored them at 4° for up to 1 month before use. Supporting Information, File S1 lists the genotypes and molecular lesions of all strains used in this study.

unc-16 forward genetic suppressor screen

We mutagenized 9000 L4's of the strain KG3035 *ceIs134* (unc-17::CTNS-1-RFP, unc-17::GFP) with 27.6 mM EMS in M9 supplemented with OP-50 bacteria for 4 hr at 20°. After growing this P_0 generation for 72 hr at 14° on four spread plates, we bleach-treated the cultures to release the F_1 generation eggs, dispensed the eggs to a single locomotion plate, and allowed them to hatch overnight at 23°. F_1 hatchlings were collected and counted, and 3000 were plated on each of 16 spread plates and grown for 24 hr at 14° + 54 hr at 23° to produce gravid F_1 adults. We then bleach-treated the F_1 adults to release the F_2 generation eggs, dispensed the eggs onto three unseeded NGM-LOB plates, and then allowed them to hatch overnight at 20°. F_2 hatchlings were collected in M9 buffer and counted, and 5000 were plated on each of 18 spread plates. Half of these plates were grown for 48 hr at 20° and half were grown for 48 hr at 14° + 24 hr at 20° so that screening could be done on 2 successive days. These growth times produced mid-L4 stage synchronous F_2 grandprogeny. For each half day of screening, we harvested animals from three of these plates by adding 5 ml of sterile PBS per plate and transferring the suspension to 8 ml of sterile PBS, stirring slowly in a 50-ml beaker. We counted 12, 50-μl aliquots of this suspension, obtained an average concentration, and adjusted the concentration to 24 worms per 50 μl. At 20-min intervals, we pipetted 50 μl (~24 worms) from the stirring suspension into each of the 12 center wells of a 96-well Mat-Tek glass-bottom plate (Mat-Tek, Ashland, MA; P96G-1.5-F-F) that had been preloaded with 50 μl of 300 μM Levamisole per well. We began screening 10 min after loading the first well and screened the animals in the 12 wells over the next 20 min using a 0.75-numerical aperture, ×20 dry objective on a Nikon TE-2000E inverted microscope with a Universal stage containing an inset for 96-well plates. In each half day of screening, over 2 successive days per week, we screened nine such rows of 12 wells. We screened animals in each well for decreased CTNS-1-RFP fluorescent puncta in the dorsal cord. At the end of each 20 min screening session, after noting the wells containing mutants, we pipetted the contents of each mutant-bearing well onto a predried streak plate using a Pasteur pipette; rinsed the well with 100 μl of M9; and then, immediately after the liquid dried in, clonally distributed up to 24 animals to a 96-well solid-media culture plate containing a thick layer of OP-50 bacteria (see *Worm culture and strains*). Depending on the relative size of the mutant animal, we often did not plate animals that were outside the relative size range observed for the mutant. After 4 d at 20°, we used a sterile toothpick to pick approximately six L4 larvae from each well into Mat-Tek wells containing 150 μM Levamisole. After rescreening on the inverted microscope, we noted wells with 100% mutant phenotype and used the corresponding well on the 96-well plate to score behavioral and other phenotypes and to set up stocks. We screened 24,192 F_2 animals for a calculated 3.5-fold genomic coverage, taking into account an experimentally determined 23% loss of animals during recovery of the mutant.

Complementation tests and mapping of new mutations

For complementation tests we crossed *unc-16(ce483)*; *ceIs134* males to *mut-1*; *unc-16(ce483)*; *ceIs134* hermaphrodites (where *mut-1* is the unknown mutation). After 3 d at 23° we tested for X-linkage by scoring L4 males from the cross for the CTNS-1-RFP phenotype in Mat-Tek wells on the inverted microscope. After allowing cross-progeny to grow an additional day at 20°, we crossed *mut-1/+*; *ce483*; *ceIs134* males to *mut-2*; *unc-16(ce483)*; *dpy-11(e224) ceIs134* (using *dpy-11* as a marker for self-progeny), where *mut-2* was *ce749*. After 3 days at 23°, we determined whether the two mutations complemented or noncomplemented by scoring L4 hermaphrodite progeny from this cross in Mat-Tek wells on the inverted scope for the CTNS-1-RFP suppressor phenotype. By this method we determined that *ce748*, *ce749*, *ce755*, and *ce757* are allelic, that *ce759* is an allele of a different X-linked gene, and that *ce752* is an allele of a different autosomal gene. To map selected mutations, we crossed the *ceIs134* transgene into the CB4856 mapping strain 12 times and then used *ceIs134* [CB4856] males to cross the CB4856 polymorphisms through a *mut-1*; *ce483*; *ceIs134* strain (where *mut-1* is the unknown mutation). We cloned 20 non-Unc-16 L4 hermaphrodites from this cross and, after 4 days at 23°, cloned 96 Unc-16 or Mut-1; Unc-16 animals from the next generation to 24-well plates. After 3 days at 23°, we then scored the L4-stage progeny of these animals in Mat-Tek wells on the inverted microscope for the CTNS-1-RFP phenotype to identify the 24-well plate addresses containing homozygous *mut-1* animals that had been crossed through the CB4856 mapping strain. We then used such lines to map the mutation relative to single nucleotide polymorphisms (SNPs) as previously described (Schade *et al.* 2005). By this method we mapped *ce749* and *ce753* to the same subregion of X and *ce759* to a different subregion of X, and we also determined that *ce752* is loosely linked to *unc-16* on chromosome III.

Whole-genome sequencing and identification of new mutations

To produce genomic DNA for whole-genome sequencing, we plated ~25 larvae onto each of two spread plates and grew them to starvation (8 days at 23°). We harvested larvae by adding 4 ml TEEN (24 g Tris base, 37 g EDTA, 23 g NaCl/ liter; pH 7.5 with 1 N HCl) per plate and collecting them by

centrifugation for 2 min at 1500 × g into a 15-ml conical tube. We then removed the supernatant by vacuum suction, washed twice with 12 ml of TEEN, spinning as above after each wash, and resuspended the final worm pellet in ~200 μl of TEEN in a 1.5-ml snap-cap tube. After centrifuging for 30 sec at 14,000 × g, we removed the supernatant, froze the tubes in liquid nitrogen, and thawed them at room temp for 1.5 min followed by incubation in a 65° temperature block for 1 min. We then followed the manufacturer's instructions for DNEasy preps (Qiagen) to purify genomic DNA from the samples. To produce libraries for whole-genome sequencing, we quantified the DNA concentrations using the Qubit fluorimeter (Invitrogen) and the Qubit dsDNA BR Assay Kit (Invitrogen), sheared the DNAs to ~350 bp by transferring 1080 ng of each DNA in 60 μl of water to Covaris Microtubes using two 25-sec cycles in a Covaris S2 at 4°, and then followed the manufacturer's instructions for the NEBNext Ultra DNA Library Prep Kit for Illumina (NEB E7370S) and NEBNext Multiplex Oligos for Illumina (Index Primers set 1 and set 2; E7335S and E7500S). We analyzed the average size and concentration of the fragments in each library using the Agilent 2200 Tape Station and adjusted the concentration of each library to equal that of the lowest concentration library. We then combined 5 μl of each library in a 250-μl screw-cap tube and submitted the combined samples for sequencing using the Rapid Run PE100 protocol on a single flow cell on a HiSequation 2500 (Illumina). We analyzed the sequences using "Whole Genomes," which is a set of web-based applications produced by Bob Barstead for analyzing whole-genome sequences. For sequence alignment to *C. elegans* sequences, we used the analysis pipeline "BWA/ GATK C. elegans WS220 SNP/Indels single RG dups allowed.".= We then used the resulting alignment file (in VCF format) to produce annotated lists of mutations by using the "Annotate Points" feature of Whole Genomes. We used the "Comparison" feature to subtract-out mutations that were common to another mutant isolated in the same genetic screen and "Filters" to specify homozygosity of mutations, high-quality "PASS" sequences, and nonsilent GC-to-AT mutations (as are produced by the EMS mutagen) and to restrict the analysis to the specific intervals of the genome where we mapped the mutations.

Plasmids

File S1 lists all of the plasmids used in this study along with sources and/or construction details. In all constructs involving the cloning of PCR fragments, we sequenced the inserts and used clones containing no mutations in the fragment of interest to make the final stock.

Production of transgenes and genomic insertions

We prepared plasmids for microinjection using the Qiagen Tip-20 system according to the manufacturer's instructions, except that we added a 0.1 M potassium acetate/2 vol ethanol precipitation step after resuspending the isopropanol-precipitated pellet. We produced transgenic strains bearing

extrachromosomal arrays by the method of Mello *et al.* (1991). For the *cdk-5* rescue experiment, the host was KG2430 *ceIs56*, and we crossed the *ceEx450* transgene into *unc-16(ce483)*; *ceIs56*. For the *sad-1* and *syd-2* rescue experiments, the hosts were KG4498 *unc-16(ce483)*; *sad-1(ce749) ceIs56* and KG4563 *unc-16(ce483)*; *syd-2(ok217) ceIs56*, respectively. For all other injection experiments, N2 was the host. We used pBluescript carrier DNA to bring the final concentration of DNA in each injection mixture to 175 ng/μl and integrated the transgenes into the genome using 9100 Rads of gamma rays as described (Reynolds *et al.* 2005). File S1 lists all the transgenes in this study, their DNA contents, and the injection concentration of each DNA. We mapped the insertion sites of *ceIs259* and *ceIs267* by crossing the integrant through CB4856, re-isolating and cloning homozygous animals in the F_2 generation, and using the resulting mapping lines to map the integration sites relative to SNPs as described (Schade *et al.* 2005).

Strain constructions

We outcrossed the strains bearing the *ce749*, *ce753*, *ce759*, and *ok217* mutations two, two, two, and three times, respectively, before using them for the experiments in this article. File S1 includes a table of all the mutations used in this study and the methods we used to genotype/confirm homozygosity of each mutation during strain constructions. To cross an integrated transgene into a mutant background, we typically crossed a male integrant strain made by the heat-shock method (Sulston and Hodgkin 1988) to the mutant, although in some cases we used integrant/+ heterozygous males. After incubating 3 days at 20°, we cloned five L4-stage cross-progeny carrying the fluorescently marked transgene. After 4 days at 23°, we cloned 12 bright fluorescent (putatively homozygous for the transgene) mutant adult hermaphrodites and grew them for 4 days at 23° before choosing one homozygous mutant line (genotyped/confirmed as indicated in File S1) that was also homozygous for the transgene to make the stock. To construct strains carrying two mutations plus a transgene, we typically first crossed the insertion into each single mutant and then used homo- or hemizygous integrant males for the first cross to mutant A, allowing the entire construction to be done in a background that is homozygous for the insertion. We constructed these strains, as well as the double mutants used for the locomotion assays (the latter lacking transgenes), using the standard method of crossing heterozygous males of mutant A with homozygous hermaphrodites of mutant B and cloning virgin F_1 cross-progeny. From plates segregating mutant A in their F_2 progeny, we cloned mutant A and/or mutant B animals and looked for segregation of the double mutant in the next generation using behavioral phenotypes (for doubles involving *unc-16*, *syd-1*, and/or *syd-2*) or genotyping as indicated in File S1. After making a strain composed of two or more mutations, we confirmed the homozygosity of each mutation using the methods described in the mutations table in File S1.

Quantitative fluorescence imaging and image analysis of organelle marker distributions

File S1 provides the detailed procedures that we used for quantitative fluorescence imaging and image analysis, including growth and mounting of strains, image acquisition, processing images, quantifying images, and producing representative images.

Time-lapse video microscopy of organelle movements in live animals

File S1 provides the detailed procedures that we used for time-lapse imaging, including growth and mounting of strains, image acquisition, processing time-lapse images, quantifying movements from kymographs, pause analysis, and producing time-lapse movies.

Locomotion rate assays

Previous studies described the basal locomotion rate assays (Miller *et al.* 1999; Reynolds *et al.* 2005). We kept the temperature at the assay location at 22°–23.5°.

Statistical analysis

We performed all statistical comparisons using the unpaired *t*-test, Welch-corrected (for comparisons between two selected groups), or ANOVA followed by the Tukey–Kramer post-test (for comparisons involving three or more groups) or Fisher's exact test (as indicated) using Graphpad Instat 3 (Graphpad Software). The *P*-value cutoff for statistical significance was ≤0.05.

Data availability

Strains and reagents are available upon request. File S1 contains Supplemental Materials and Methods and a detailed description of all of the strains, plasmids, and transgenes produced in this study.

Results

A forward genetic screen reveals a role for CDK-5, SAD-1, and SYD-2 in promoting the axonal accumulation of lysosomes in unc-16 mutants

To identify proteins that contribute to the axonal accumulation of organelles in *unc-16* mutants, we screened the grandprogeny of EMS-mutagenized *unc-16* mutants for suppressor mutants in which lysosomes in the dorsal axons were reduced or absent. To mark lysosomes, we used a genomically integrated transgene that expresses CTNS-1-RFP in *C. elegans* cholinergic motor neurons. Prior studies confirmed that this marker, which encodes a lysosome cysteine transporter (Kalatzis *et al.* 2001), specifically localizes to lysosomes in *C. elegans* (Mangahas *et al.* 2008; Edwards *et al.* 2013). The transgene also expresses soluble GFP in the same neurons to monitor expression effects (Figure 1A). A screen of ~24,200 F_2 animals (~3.5-fold genomic coverage) netted seven mutants with few or no detectable lysosomes in their dorsal axons and normal GFP levels. Complementation tests and mapping revealed that
the seven mutations represent five alleles of one gene and single alleles of two other genes. Sequencing the genomes of these mutants and analyzing the mutations in the mapped intervals revealed that the group with five alleles had single mutations in *sad-1* (three with premature stop codon mutations and two with missense mutations), while the other two mutants had premature stop codons in *syd-2* and *cdk-5*, suggesting that the suppressor phenotypes of these mutants are all associated with loss of function. The three genes encode proteins known as SAD-1 (SAD-A Kinase), SYD-2 (Liprin-α), and CDK-5 (Cyclin-dependent Kinase 5) (Figure 1, B and C).

CDK-5, SAD-1, and SYD-2 act together to promote axonal lysosome accumulation in an unc-16 null mutant

To quantify the extent to which eliminating the function of each of these proteins affects the distribution of CTNS-1-RFP lysosomes in neurons in *unc-16(+)* and *unc-16(−)* backgrounds, we crossed putative null mutations of each gene into an integrated transgene background that expresses CTNS-1-RFP in a subset of nine cholinergic motor neurons in which the axons, cell somas, and dendrites of each motor neuron are segregated and thus easily identifiable (Figure 2A). For these experiments, we used the independently isolated deletion alleles *cdk-5(gm336)* and *syd-2(ok217)* along with the *sad-1(ce749)* premature stop codon allele, and we quantified both the number of puncta per micrometer exceeding a predefined threshold (lysosome punctal density) and the total fluorescence per micrometer of axon length (CTNS-1-RFP fluorescence/μm). The total fluorescence/μm parameter includes both lysosome puncta and nonpunctal CTNS-1-RFP fluorescence.

In an *unc-16(+)* background, wild-type and all three single mutants had lysosome punctal densities of zero. Wild type's CTNS-1-RFP fluorescence/μm was ~12% of the *unc-16* null mutant, and neither the *cdk-5* nor the *sad-1* single mutant was significantly different from the wild type. The *syd-2* mutant was slightly, but significantly, lower at ~6% of the *unc-16* mutant (Figure 2B).

In an *unc-16(−)* background, the lysosomal punctal density was strongly reduced in the *unc-16 cdk-5*, *unc-16; sad-1*, and *unc-16; syd-2* doubles relative to *unc-16* single mutants, thus confirming the suppression phenotype that we detected in the genetic screen. The strongest reduction occurred in the *unc-16 cdk-5* double (~3% of *unc-16*), whereas *sad-1* and *syd-2* doubles showed reductions to 12 and 26% of *unc-16*, respectively. All three doubles showed similar but smaller reductions in fluorescence/μm (to ~50% of wild type; Figure 2C). Independently isolated alleles of *sad-1* and *syd-2* showed quantitatively similar reductions in lysosome punctal density and fluorescence (data not shown). In addition, expressing *cdk-5*, *sad-1*, or *syd-2* transgenically in the same neurons significantly rescued the suppression phenotype in *unc-16 cdk-5*, *unc-16; sad-1*, and *unc-16; syd-2* double mutant axons, demonstrating that all three proteins function in the motor neurons that express the *unc-16* suppression phenotype (Figure S1B).

Figure 1 Forward genetic screen for mutations that suppress axonal lysosome accumulation in *unc-16* mutants. (A) Drawings illustrate the forward genetic screen for *unc-16* suppressor mutants. The screen used EMS to mutagenize an *unc-16* null mutant carrying the integrated transgene *ceIs134*, which uses the unc-17β promoter to co-express CTNS-1-RFP (to mark lysosomes) and GFP (as an expression control) in the ventral cord cholinergic motor neurons. We screened the F₂ grandprogeny of mutagenized animals on 96-well glass-bottom Mat-Tek plates using an inverted microscope and selected animals with few or no lysosomes in their dorsal axons and normal GFP expression. (B) Summary of mutations identified in the *unc-16* suppressor screen. "Conserved" means that the amino acid is conserved in the human ortholog of SAD-1, known as SAD-A/B or BRSK2. *ce753* and *ce755* are weaker suppressors of *unc-16* than the *sad-1* nonsense mutants, and they contain some lysosomes in their dorsal axons. (C) Representative images of wild-type, the *unc-16* mutant, and a double mutant carrying the *unc-16* null mutation in combination with one of the suppressor mutations. Lysosomes (red puncta) are inside GFP-labeled cholinergic motor neurons (green).

To determine whether the *cdk-5*, *sad-1*, and *syd-2* mutations disrupt the same or different systems regulating axonal lysosome content, we analyzed all possible combinations of the mutants in *unc-16(+)* and *unc-16(−)* backgrounds and compared their axonal lysosome density and fluorescence/µm parameters to the component single mutants. In an *unc-16(+)* background, none of the mutant combinations differed significantly from the component mutants from which they were constructed for either parameter (*i.e.*, they all showed zero puncta and had low fluorescence levels similar to wild type; Figure 2B). In an *unc-16(−)* background, none of the mutant combinations, including the *unc-16 cdk-5*; *sad-1 syd-2* quadruple mutant, showed a significant difference in lysosomal punctal density relative to the lowest level of any individual component mutant. However, for the fluorescence/µm parameter, the *unc-16 cdk-5*; *sad-1* triple mutant and the *unc-16 cdk-5*; *sad-1 syd-2* quadruple mutant showed significant reductions when compared to the *unc-16*; *sad-1* double mutant, and the *unc-16 cdk-5*; *syd-2* triple mutant showed a significant reduction when compared to *unc-16*; *syd-2*. However, these reductions were relatively minor, decreasing from 50% of the *unc-16* single mutant to 39, 31, and 31%, respectively, and none of the other mutant combinations showed a significant difference when compared to the lowest level of the component mutants (Figure 2C).

In summary, although these results show that the three proteins do not have equally important roles (CDK-5 apparently having the strongest role, at least for lysosomal punctal density), they do suggest that CDK-5, SAD-1, and SYD-2 largely act together and cell-autonomously as part of a system that promotes axonal lysosome accumulation in the absence of UNC-16. In addition, because elimination of CDK-5, SAD-1, or SYD-2 strongly suppresses axonal lysosome accumulation in *unc-16* mutants, the data are consistent with UNC-16 directly or indirectly inhibiting the CDK-5/SAD-1/SYD-2 system from promoting axonal accumulation of lysosomes.
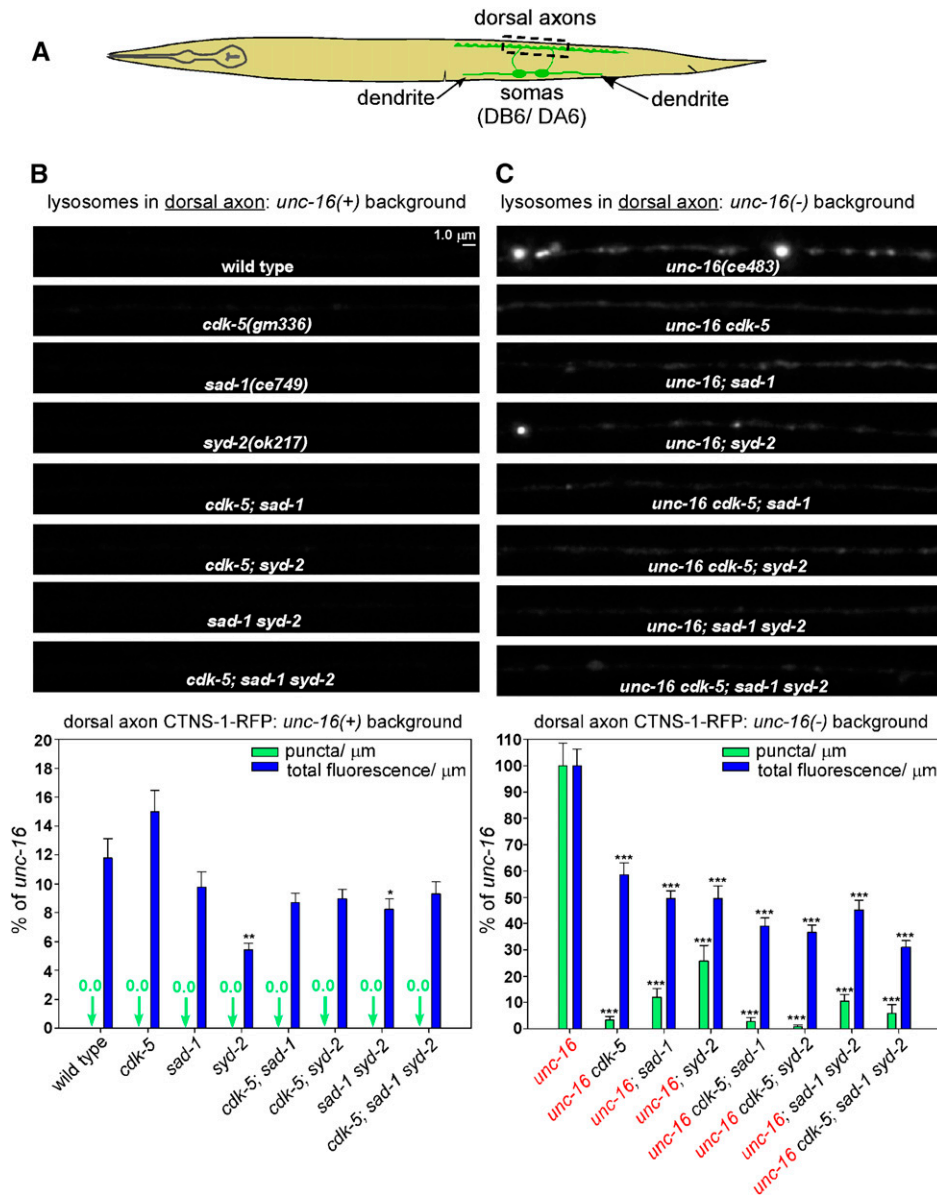

Figure 2 CDK-5, SAD-1, and SYD-2 act together to promote axonal lysosome accumulation in an *unc-16* null mutant. (A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed box outlines the region imaged. (B and C) Representative, identically scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micrometer of the indicated genotypes in an *unc-16(+)* background (B) or an *unc-16(−)* background (C). CTNS-1-RFP is expressed from the integrated transgene *cels56*. Data are means and SEMs from 13–14 animals. Asterisks indicate values significantly different from wild type (B) or *unc-16* (C): *$P <$ 0.05; **$P <$ 0.01; ***$P <$ 0.0001. For lysosome punctal density in an *unc-16(−)* background, none of the CCS mutant combinations differed significantly from the component single mutants. However, for the fluorescence/μm parameter, the *unc-16 cdk-5*; *sad-1* triple mutant and the *unc-16 cdk-5*; *sad-1 syd-2* quadruple mutant showed small but significant reductions when compared to the *unc-16*; *sad-1* double mutant ($P =$ 0.02 and $<$0.0001), and the *unc-16 cdk-5*; *syd-2* triple mutant showed a small but significant reduction when compared to *unc-16*; *syd-2* ($P =$ 0.03).

CDK-5, SAD-1, and SYD-2 act together to inhibit dendritic lysosome accumulation in an unc-16 null mutant

We next investigated how the same mutations affect the lysosome content of dendrites. In an *unc-16(+)* background, wild type had a relatively low lysosomal punctal density in its dendrites, averaging ~1 puncta every 52 μm in the region bounding the DA6/DB6 motor neurons. Dendritic lysosomal puncta density and fluorescence/μm for *sad-1* and *syd-2* single mutants were not significantly different from wild type; however, the levels of puncta and fluorescence in *cdk-5* single mutants were significantly higher (approximately two-fold), demonstrating that CDK-5 has a role in regulating dendritic lysosome content even in the presence of wild-type UNC-16 (Figure 3, A and B).

Similar to *cdk-5* single mutants, *unc-16* mutants had dendritic levels of lysosomal puncta and fluorescence that were ~2-fold higher than wild type. However, the *unc-16 cdk-5* double showed a nonadditive synthetic effect in which dendritic puncta and fluorescence levels increased to ~10-fold higher than wild type. Furthermore, even though *sad-1* and *syd-2* single mutants had wild-type levels of lysosomes in their dendrites, their doubles with *unc-16* had levels that were 6–10-fold higher than wild type (Figure 3C). Independently isolated alleles of *sad-1* and *syd-2* in doubles with *unc-16* showed quantitatively similar dendritic accumulations of lysosomes (data not shown). In addition, expressing *cdk-5*, *sad-1*, or *syd-2* transgenically in the same neurons significantly rescued the suppression phenotype in *unc-16 cdk-5*, *unc-16*; *sad-1*, and *unc-16*; *syd-2* double mutant dendrites, demonstrating that all three proteins function in the motor neurons that express the *unc-16* suppression phenotype (Figure S1C).

To determine whether the *cdk-5*, *sad-1*, and *syd-2* mutations disrupt the same or different systems for regulating
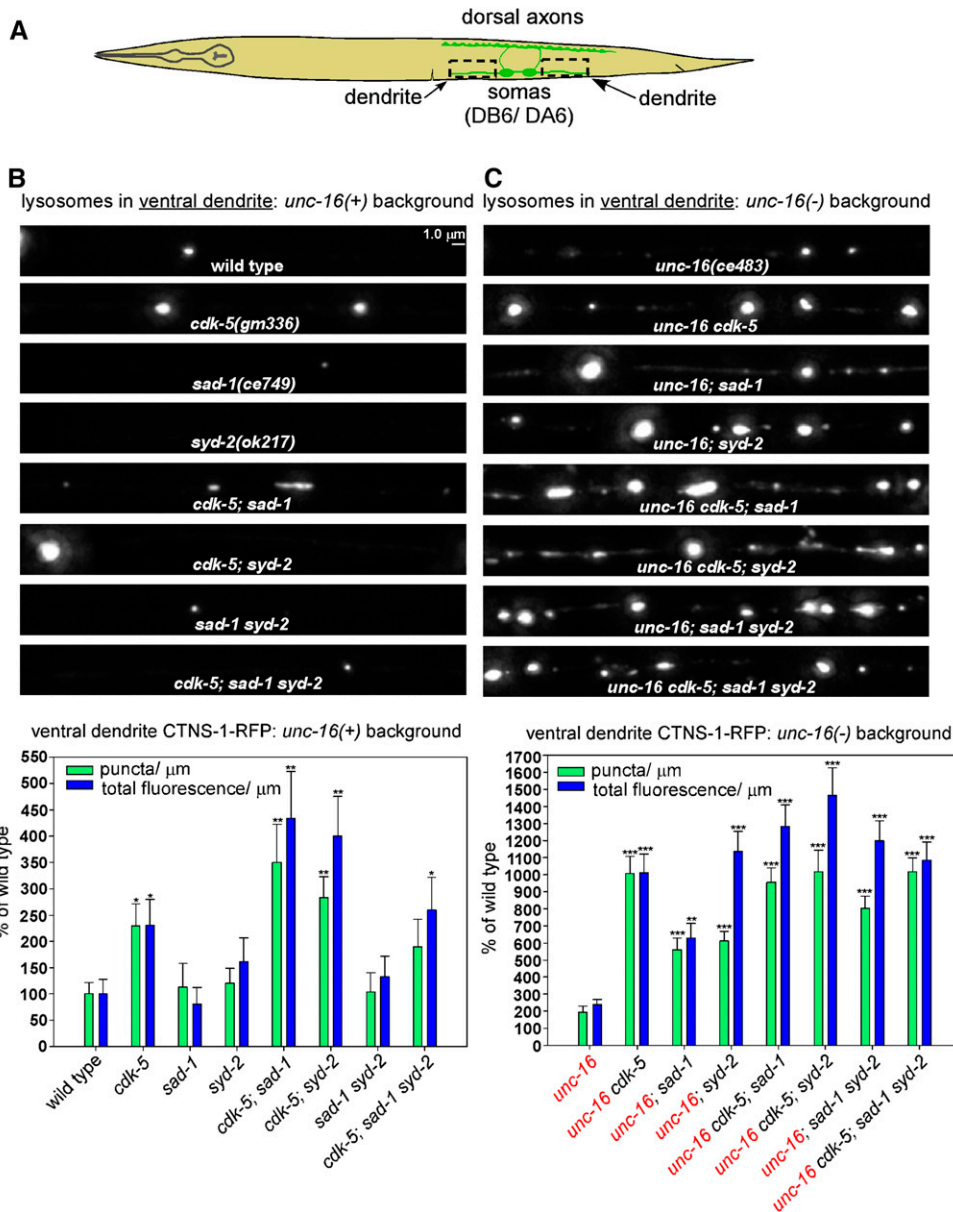

Figure 3 CDK-5, SAD-1, and SYD-2 act together to inhibit dendritic lysosome accumulation in an *unc-16* null mutant. (A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed boxes outline the regions imaged (both dendrites were imaged together and then combined for quantification). (B and C) Representative, identically scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micrometer of the indicated genotypes in an *unc-16(+)* background (B) or an *unc-16(−)* background (C). CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. Data are means and SEMs from 13–14 animals. Asterisks indicate values significantly higher than wild type (B) or *unc-16* (C): *$P < 0.05$; **$P < 0.01$; ***$P < 0.0001$. None of the mutant combinations in *unc-16(+)* or *unc-16(−)* backgrounds, including the *unc-16 cdk-5; sad-1 syd-2* quadruple mutant, showed a significant difference in dendritic lysosomal punctal density compared to the highest level of any individual component mutant. However, for the fluorescence/μm parameter, the *unc-16 cdk-5; syd-2* triple mutant was significantly higher than the *unc-16; cdk-5* double mutant ($P = 0.03$).

dendritic lysosome content, we analyzed all possible combinations of the mutants in *unc-16(+)* and *unc-16(−)* backgrounds and compared their dendritic puncta and fluorescence levels to the component single mutants. None of the mutant combinations in *unc-16(+)* or *unc-16(−)* backgrounds, including the *unc-16 cdk-5; sad-1 syd-2* quadruple mutant, showed a significant difference in dendritic lysosomal punctal density compared to the highest level of any individual component mutant. However, for the fluorescence/μm parameter, the *unc-16 cdk-5; syd-2* triple mutant was 1400% of wild type, which was a significant increase compared to the *unc-16; cdk-5* double mutant (1000% of wild type). However, none of the other mutant combinations in *unc-16(+)* or *unc-16(−)* backgrounds, including the quadruple mutant, showed a significant difference in fluorescence/μm compared to the highest level in the component mutants (Figure 3, B and C).

We also analyzed cell soma levels of CTNS-1-RFP-labeled lysosomes in the same set of mutants and found that *cdk-5*, *sad-1*, and *syd-2* loss-of-function mutations are associated with significant, albeit mild-to-moderate, decreases in lysosomes (∼60–90% of the *unc-16* single mutant; Figure S2). This is consistent with a relatively slow loss of lysosomes to the dendrite in these mutants (*i.e.*, at a rate that allows cell soma levels to remain relatively stable) and also shows that effects on expression of the transgene are not the cause of the increased dendritic lysosome levels.

In summary, although the results again show that the three proteins do not have equally important roles (CDK-5 and SYD-2 apparently having the strongest roles), they do suggest that CDK-5, SAD-1, and SYD-2 largely act together as part of the same general system that inhibits dendritic lysosome accumulation in the absence of UNC-16.

SYD-1 and STRD-1 (STRADα) act with the CDK-5/SAD-1/SYD-2 system to regulate axonal and dendritic lysosome trafficking in an unc-16 null mutant

A previous study found that CDK-5 acts in parallel with the cyclin-dependent Pctaire kinase PCT-1 to regulate the trafficking of synaptic vesicles in some, but not all, classes of motor neurons in *C. elegans* (Ou *et al.* 2010). To determine if CDK-5 and PCT-1 also act in parallel to regulate the distribution of lysosomes in cholinergic motor neurons, we compared *unc-16* single mutants to *unc-16 cdk-5* and *unc-16*; *pct-1* doubles and the *unc-16 cdk-5*; *pct-1* triple. For this analysis we used the null deletion allele *pct-1(tm2175)*, which removes the kinase domain in all three isoforms (Ou *et al.* 2010). The *unc-16*; *pct-1* double did have a significantly lower lysosomal punctal density in its axons compared to the *unc-16* single mutant (∼50%); however, the percentage decrease was much less than the *unc-16*; *cdk-5* double, and its CTNS-1 fluorescence/μm was not significantly different from the *unc-16* single mutant (Figure S3, A and B). The *unc-16*; *pct-1* double also had a small but significant increase in fluorescence/μm in its dendrites compared to the *unc-16* single mutant (approximately two-fold), but its punctal density was not significantly different from the *unc-16* single mutant. Also, in the *unc-16 cdk-5*; *pct-1* triple mutant, the severity of the axonal and dendritic phenotypes was not significantly increased relative to the *unc-16 cdk-5* double mutant. These results thus show that CDK-5 is the most important/relevant cyclin-dependent kinase in these neurons for lysosomal trafficking and also suggest that CDK-5 can mostly substitute for lack of PCT-1, but the reverse is not true.

Previous studies in *C. elegans* and *Drosophila* found that SYD-1 acts in the same pathway as SYD-2 to regulate synapse assembly and positioning of active zone components in motor neurons (Dai *et al.* 2006; Patel *et al.* 2006; Li *et al.* 2014). To determine whether SYD-1 and SYD-2 also act in the same system to regulate the trafficking of lysosomes in motor neurons, we compared *unc-16* single mutants to *unc-16*; *syd-1* and *unc-16*; *syd-2* doubles and the *unc-16*; *syd-1*; *syd-2* triple. For this analysis we used the null deletion allele *syd-1(tm6234)*. In the *unc-16*; *syd-1* double, the lysosomal punctal density in axons was significantly lower than the *unc-16* single mutant (∼60% of *unc-16*). This suppression phenotype was significantly weaker than the *unc-16*; *syd-2* double, which had a lysosome punctal density that was ∼25% of *unc-16*. In dendrites, the lysosomal punctal density and fluorescence/μm for the *unc-16*; *syd-1* double were significantly higher than the *unc-16* single mutant, and, in this region, the lysosomal punctal density of the *unc-16*; *syd-1* double was not significantly different from the *unc-16*; *syd-2* double. The *unc-16*; *syd-1*; *syd-2* triple was not significantly different from the *unc-16*; *syd-2* double for either parameter in axons or dendrites (Figure S3, A–C). We conclude that SYD-1 functions in the same system as SYD-2 to regulate the trafficking of lysosomes in axons and dendrites and that

SYD-2 remains partially functional in the absence of SYD-1 in its axonal lysosome trafficking role, but the reverse is not true. Neither protein is functional without the other for dendritic lysosome trafficking.

We applied a similar analysis to test for a role for NAB-1 (Neurabin) in lysosome trafficking. Previous *C. elegans* studies found that NAB-1 is an F-actin-binding protein that also directly binds SAD-1 (Hung *et al.* 2007) and SYD-1 (Chia *et al.* 2012), and that SYD-2 may form a complex with SYD-1 and NAB-1 (Chia *et al.* 2012). For this analysis, we used the *nab-1(ok943)* null deletion allele (Hung *et al.* 2007). In axons, the *unc-16*; *nab-1* double showed no significant difference when compared to the *unc-16* single for lysosomal punctal density or fluorescence/μm. In dendrites, the *unc-16*; *nab-1* double had a lysosomal punctal density that was approximately threefold higher than wild type (significantly higher than the approximately two-fold increase of the *unc-16* single) with a similar significant increase in fluorescence/μm. The *unc-16*; *sad-1*; *nab-1* and *unc-16*; *syd-2*; *nab-1* triples were not significantly different from the corresponding *unc-16*; *sad-1* and *unc-16 syd-2* doubles for either parameter in axons or dendrites (Figure S4, A–C). We conclude that NAB-1 does not have a nonredundant role in preventing the axonal accumulation of lysosomes in *unc-16* mutants. In dendrites, it appears to have a minor role in inhibiting lysosome accumulation in *unc-16* mutants, and this minor function overlaps with the functions of SAD-1 and SYD-2.

Continuing our search for other proteins that may act with the CDK-5/SAD-1/SYD-2 system to regulate lysosome trafficking in neurons, we applied a similar analysis to test for a role for STRD-1 (STRADα), a STE-20-related pseudokinase. A previous *C. elegans* study found that STRD-1 forms a complex with SAD-1 and that loss-of-function mutations in *strd-1* and *sad-1* show similar neuronal phenotypes (Kim *et al.* 2010). For this analysis, we used the *strd-1(ok2283)* null deletion allele (Kim *et al.* 2010). Like the *sad-1* single mutant, *strd-1* single mutants in an *unc-16(+)* background showed no significant increase in dendritic lysosomes for either parameter (S. L. Edwards and K. G. Miller, unpublished results). In axons, similar to the *unc-16*; *sad-1* double mutant, the *unc-16*; *strd-1* double showed significantly lower levels than the *unc-16* single mutant for lysosomal punctal density and fluorescence/μm. However, its suppressor phenotype, which was ∼38 and 65% of the *unc-16* single mutant for lysosomal punctal density and fluorescence/μm, respectively, was significantly weaker than that conferred by the *sad-1* mutant (which was ∼12 and 50% of the *unc-16* single mutant, respectively). In dendrites, the *unc-16*; *sad-1* and *unc-16*; *strd-1* doubles were not significantly different for either parameter. The *unc-16*; *sad-1*; *strd-1* triple mutant showed no significant differences for either parameter in axons or dendrites when compared to *unc-16*; *sad-1* (Figure S5, B and C). We conclude that STRD-1 (STRADα) and SAD-1 are part of the same system to regulate the trafficking of lysosomes in axons and dendrites. The data further show that neither protein can function without the other in

regulating dendritic lysosome trafficking, but SAD-1 remains partially functional in the absence of STRD-1 for axonal lysosome trafficking.

KIF1A (UNC-104) is not the motor that carries lysosomes to the axonal synaptic region in unc-16 mutants

In the accompanying article in this issue, we found that the synapse assembly proteins SYD-1, SYD-2, and SAD-1 promote the plus-end-directed trafficking of synaptic vesicles by the kinesin KIF1A (UNC-104), preventing their accumulation in dendrites and cell somas in *C. elegans* cholinergic motor neurons (Edwards *et al.* 2015). However, UNC-104 does not contribute to the accumulation of lysosomes in *unc-16* mutant axons because, when we compared *unc-16* single mutants to *unc-16; unc-104* doubles, the cell soma and axonal levels of lysosomes in motor neurons in the *unc-16; unc-104* double were not significantly lower than the *unc-16* single mutant (Figure S6). For this analysis we used the *unc-104(e1265)* allele, which contains a missense mutation in the cargo-binding domain that causes a strong loss of function (Kumar *et al.* 2010), but we also obtained the same result using the motor domain temperature-sensitive allele *unc-104(ce782)* (Edwards *et al.* 2015), which we analyzed at the restrictive temperature of 20° (data not shown).

cdk-5 and sad-1 null mutations also suppress the sluggish locomotion of an unc-16 null mutant

unc-16 null mutants have sluggish spontaneous locomotion rates that are ~10% of wild type (Edwards *et al.* 2013). We considered the possibility that the abnormal presence of high levels of cell soma organelles in motor neuron axons might directly or indirectly impair neuronal function and, in so doing, might contribute to the sluggish locomotion phenotype. If this is the case, then mutations that suppress axonal organelle accumulation in *unc-16* mutants should also improve their locomotion. To test this, we quantified the locomotion rates of wild type and *cdk-5*, *sad-1*, and *syd-2* mutants in *unc-16(+)* and *unc-16(−)* backgrounds. For this analysis, we tested two independently isolated null or loss-of-function alleles of each gene. In an *unc-16(+)* background, none of the single mutants had locomotion rates that were significantly slower than wild type, although one of the *cdk-5* mutants had a slightly, but significantly, higher locomotion rate (Figure 4A). However, depending on the allele used, *unc-16 cdk-5* and *unc-16; sad-1* double mutants showed significant ~2.3–4.5-fold improvements in their locomotion rates compared to *unc-16* single mutants (Figure 4B). *unc-16; syd-2* double mutants did not show improved locomotion compared to the *unc-16* single. However, we also noted that *unc-16; syd-2* doubles had synthetic phenotypes such as slower growth and short body length, and the extent to which these and other possible synthetic phenotypes that affect neuronal function in unknown ways might contribute to their overall locomotion rate is unclear.

In summary, although such whole-animal behavioral data cannot allow us to make a causal conclusion about the extent to which the accumulation of cell soma organelles in axons impairs neuronal function, they demonstrate a significant correlation.

Accumulation of lysosomes in the dendrites of unc-16 cdk-5 and unc-16; syd-2 double mutants is dynein-dependent

In *C. elegans* motor neurons, including the DA6/DB6 motor neuron pair that we imaged in this study, axonal microtubules are primarily plus-end-out and dendritic microtubules are largely minus-end-out (Goodwin *et al.* 2012; Yan *et al.* 2013). Because the *unc-16* suppressor mutations lead to the depletion of lysosomes from axons and their accumulation in dendrites, we tested the hypothesis that this redistribution is dependent on the minus-end motor dynein by comparing *unc-16; cdk-5* and *unc-16; syd-2* mutants in *nud-2(+)* and *nud-2(−)* backgrounds. *nud-2* encodes the *C. elegans* ortholog of the *Aspergillus nidulans* NUDE protein (known as NUDEL and Nde1 in vertebrates), which forms a complex with the dynein regulator LIS1 and dynein heavy chain (Niethammer *et al.* 2000; Sasaki *et al.* 2000) that may stimulate the transport of acidic organelles upon phosphorylation by Cdk5 (Pandey and Smith 2011). For this analysis we used the *nud-2(ok949)* null deletion allele (Fridolfsson *et al.* 2010), which is homozygous viable.

When we analyzed CTNS-1-RFP in axons, the *unc-16; nud-2* double did not differ from the *unc-16* single mutant for lysosomal punctal density. However, in the absence of both *unc-16* and *cdk-5*, the additional genetic ablation of *nud-2* (*i.e.*, the *unc-16; nud-2; cdk-5* triple) resulted in a 14-fold increase in axonal lysosomal punctal density, to ~60% of the *unc-16* single, and increased axonal fluorescence/μm to ~82% of the *unc-16* single. Similarly, ablating *nud-2* restored the axonal lysosomal punctal density of the *unc-16; syd-2* double mutant from ~30% of the *unc-16* single to a level not significantly different from the *unc-16* single and increased its fluorescence/μm to a level significantly higher than the *unc-16* single (Figure 5B).

In dendrites, we found that ablating *nud-2* restored the approximately two-fold increase seen in *unc-16* single mutants to levels not significantly different from wild type for both punctal density and fluorescence/μm. However, we observed a much larger effect of the *nud-2* ablation on the dendritic lysosome content of the *unc-16 cdk-5* double, where CTNS-1-RFP levels decreased from >10-fold higher than wild type in the *unc-16 cdk-5* double to levels not significantly different from the *unc-16* single in the *unc-16; nud-2; cdk-5* triple. The *nud-2* mutation had similar effects on the *unc-16; syd-2* double, although dendritic lysosome levels in the *unc-16; nud-2; syd-2* triple were still significantly higher than the *unc-16* single (Figure 5D). Lysosome levels in the cell soma were not significantly affected in the strains used for this experiment (Figure S7, A and B).
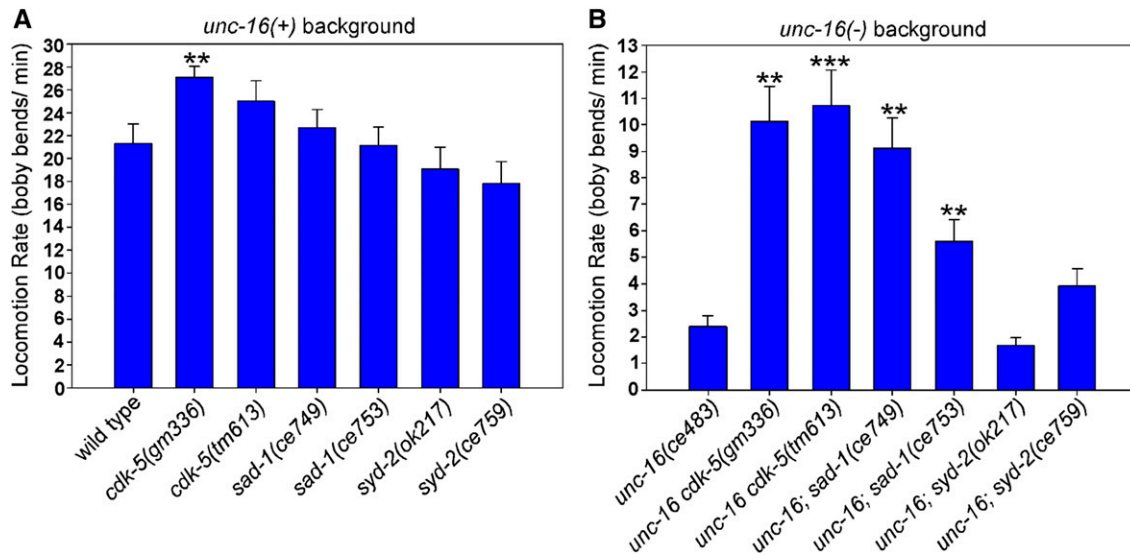

Figure 4 Eliminating CDK-5 or SAD-1 improves the locomotion rate of an *unc-16* null mutant. (A and B) Locomotion rates of the indicated genotypes in *unc-16(+)* (A) and *unc-16(−)* (B) backgrounds. Data are means and SEMs from 10 animals. ***P* < 0.01 and ****P* < 0.0001, respectively, when compared to wild type (A) or *unc-16(ce483)* (B). Unmarked bars are not significantly different from the wild-type (A) or *unc-16(ce483)* (B) controls.

In summary, these data suggest that the loss of lysosomes from the axons of *unc-16 cdk-5* and *unc-16; syd-2* double mutants, and the accumulation of lysosomes in the dendrites of the same mutants, is dependent on the minus-end motor dynein.

### CDK-5, SAD-1, and SYD-2 regulate dendritic lysosome transport even in an UNC-16(+) background

In a previous study we found that, in wild type, lysosomes are not restricted to the cell soma, but instead move back and forth between the cell soma and the axon initial segment, only rarely moving beyond the initial segment, and even more rarely attaining the distal synaptic region in wild-type motor neurons (Edwards *et al.* 2013). However, that study did not examine lysosome movements between the cell soma and dendrite. We therefore used time-lapse imaging in living animals to view the movements of CTNS-1-RFP-tagged lysosomes both between the DB7 cholinergic motor neuron cell soma and dendrite and within the DB7 dendrite in wild-type, *cdk-5*, *sad-1*, and *syd-2* null mutants. Similar to the axon/soma boundary, we found that lysosomes in wild-type animals frequently exited the cell soma and entered the dendrite (and vice versa), either in the form of spherical (symmetrical) puncta or large multi-micrometer-long tubular organelles (Figure 6A; movie File S2). The number of exit and entry events was approximately equal, and each occurred at approximately the same rate of 8–10 events per hour at 22° (Figure 6, B and C). None of the three single mutants differed significantly from wild type in their percentage of cell-soma-to-dendrite exit events (*i.e.*, the proportion of all exit/entry events that were exit events) nor in the rates at which lysosomes entered/exited the soma to/from the dendrite (Figure 6, B and C). However, *syd-2* mutants

showed a significantly lower rate of lysosomes entering the cell soma from the dendrite compared to the rate at which lysosomes exited the cell soma to the dendrite in the same strain (Figure 6C).

Upon entering the dendrite, wild-type lysosomes spent ~42% of their time in a paused state. However, lysosomes in *cdk-5*, *sad-1*, and *syd-2* mutants spent a significantly higher percentage of their time in a paused state (60, 57, and 80%, respectively), suggesting that lysosomes in all three mutants have decreased processivity in the dendrite.

We also analyzed the directionality of lysosome movements within the dendrite. Because the dendrites of these motor neurons are oriented with their minus-ends out (Goodwin *et al.* 2012; Yan *et al.* 2013), anterograde movements (movements outward from the soma) are minus-end-directed and retrograde movements (movements toward the soma) are plus-end-directed. This analysis revealed that 55–60% of the movements in wild-type, *cdk-5*, and *sad-1* were in an antero-grade (minus-end) direction, whereas lysosomes in the *syd-2* mutant moved anterogradely (toward minus ends) 75% of the time (a difference that was significant compared to wild type; Figure 6E).

When not in a paused state, lysosomes in wild type moved anterogradely at a mean velocity of 0.45 μm/sec and retrogradely at a significantly slower mean velocity of 0.28 μm/sec. Although all three mutants shared the wild-type pattern of having retrograde movements that were significantly slower than anterograde movements, their mean anterograde and retrograde velocities were significantly slower than wild type, with the exception of the retrograde velocity in *cdk-5* mutants, which was not significantly different from wild type. Correlating with a higher percentage of time in the paused state, lysosomes in *syd-2* mutants had the slowest velocities: both anterograde
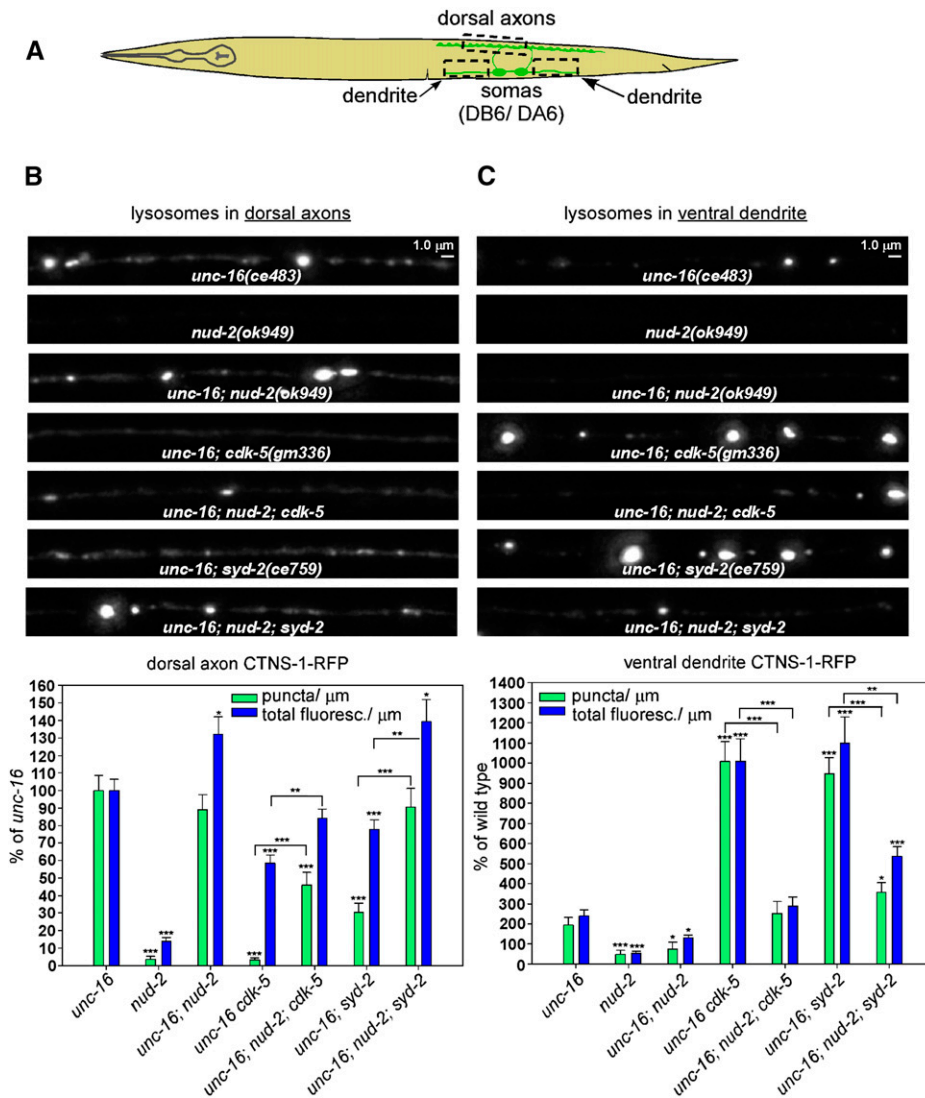

Figure 5 CDK-5 and SYD-2 prevent the dynein-dependent accumulation of lysosomes in dendrites in the absence of UNC-16. (A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed boxes outline the regions imaged. (B and C) Representative, identically scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micrometer in the dorsal axons (B) and ventral dendrites (C) of the indicated genotypes in an *unc-16(−)* background. CTNS-1-RFP is expressed from the integrated transgene *cels56*. Data are means and SEMs from 13–14 animals per region. Asterisks over bars indicate values significantly different from *unc-16*. Asterisks over brackets denote *P*-values for the selected comparisons: *$P < 0.05$; **$P < 0.01$; ***$P < 0.0001$.

and retrograde velocities were ∼55% of wild type (Figure 6F). Despite these slower velocities, the mean anterograde run lengths of wild type and the three mutants were not significantly different. The mean retrograde run length of the *cdk-5* mutant was also not significantly different from wild type; however, the *sad-1* mutant had a shorter retrograde run length that approached statistical significance ($P = 0.08$), and the *syd-2* mutant had a mean retrograde run length that was ∼50% of wild type (a highly significant difference; Figure 6G).

In summary, all three mutants showed significant differences from wild type in two or more parameters for the dendritic transport of lysosomes. Dendritic lysosomes in all three mutants spend a higher percentage of their time in a paused state and have slower anterograde (minus-end-directed) velocities when they are not in a paused state. *sad-1* and *syd-2* mutants also have slower retrograde (plus-end-directed) velocities and shorter retrograde run lengths. These phenotypes are strongest in the *syd-2* mutant, which also was the only one of the three mutants in which lyso-

somes entered the soma from the dendrite at a significantly lower rate than the rate in the reverse direction.

In an unc-16(−) background, decreased processivity and a bias toward anterograde (minus-end) movements may cause lysosomes to accumulate in dendrites in cdk-5, sad-1, and syd-2 null mutants

To investigate why lysosomes accumulate at high levels in the dendrites of *unc-16* mutants that also lack *cdk-5*, *sad-1*, or *syd-2*, we performed the same time-lapse imaging experiments on *unc-16* and all three double mutants. Similar to the results in the *unc-16(+)* background, none of the three suppressor mutants significantly affected the percentage of cell-soma-to-dendrite exit events compared to *unc-16* single mutants (Figure 7B), although all three double mutants had a lower percentage of cell soma exit events than the corresponding strains in an *unc-16(+)* background (comparing Figure 6B and Figure 7B; $P < 0.03$ for all three mutant comparisons; $P = 0.06$ when comparing wild-type and the *unc-16* single mutant). This latter result could be explained
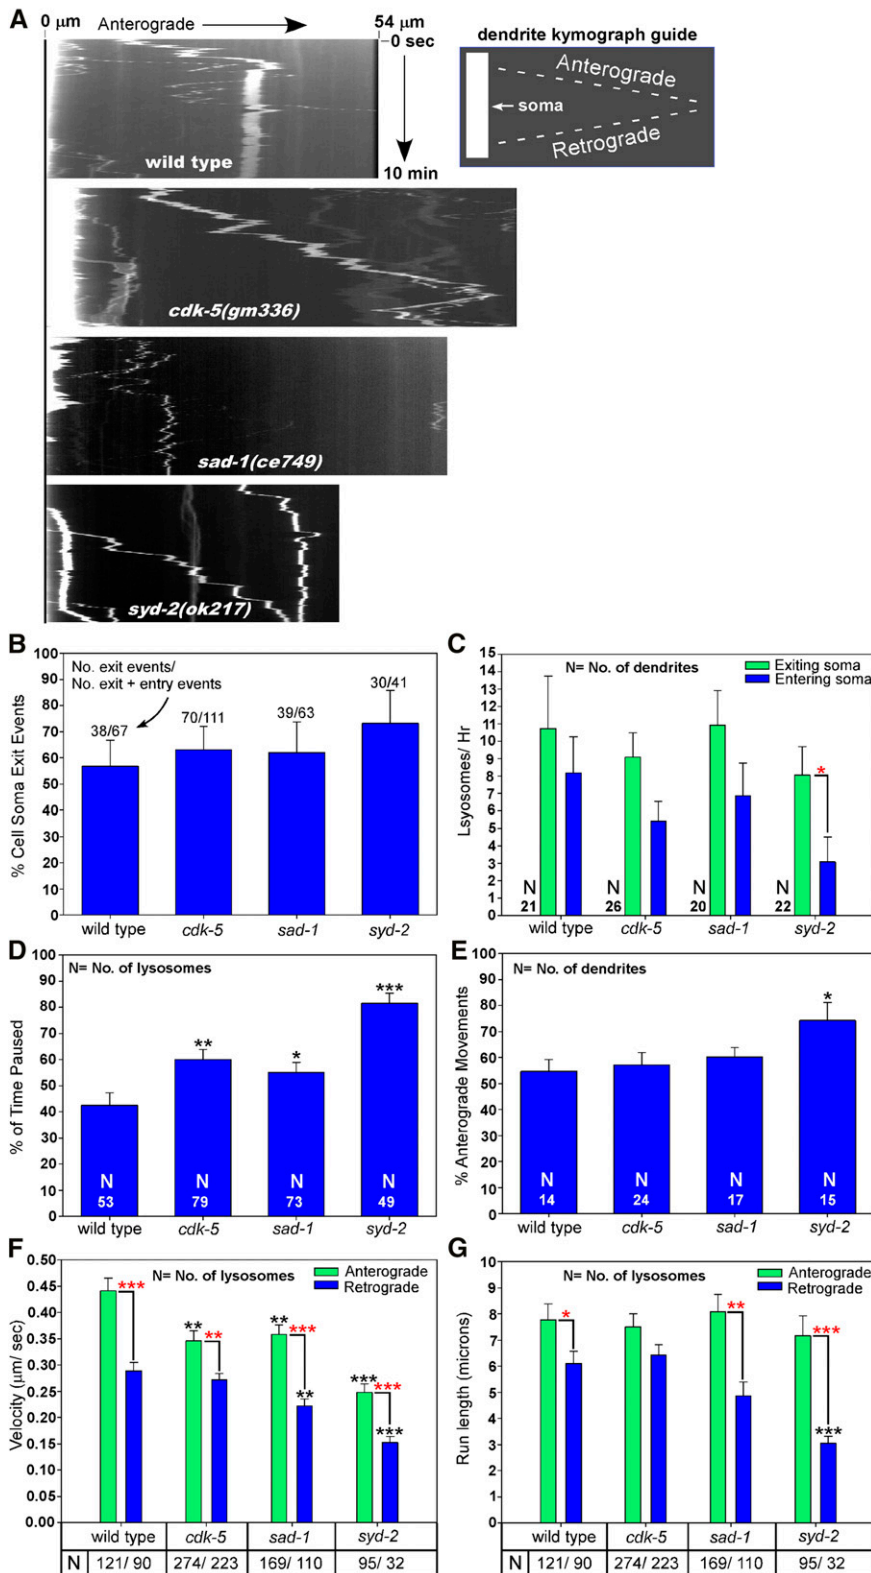

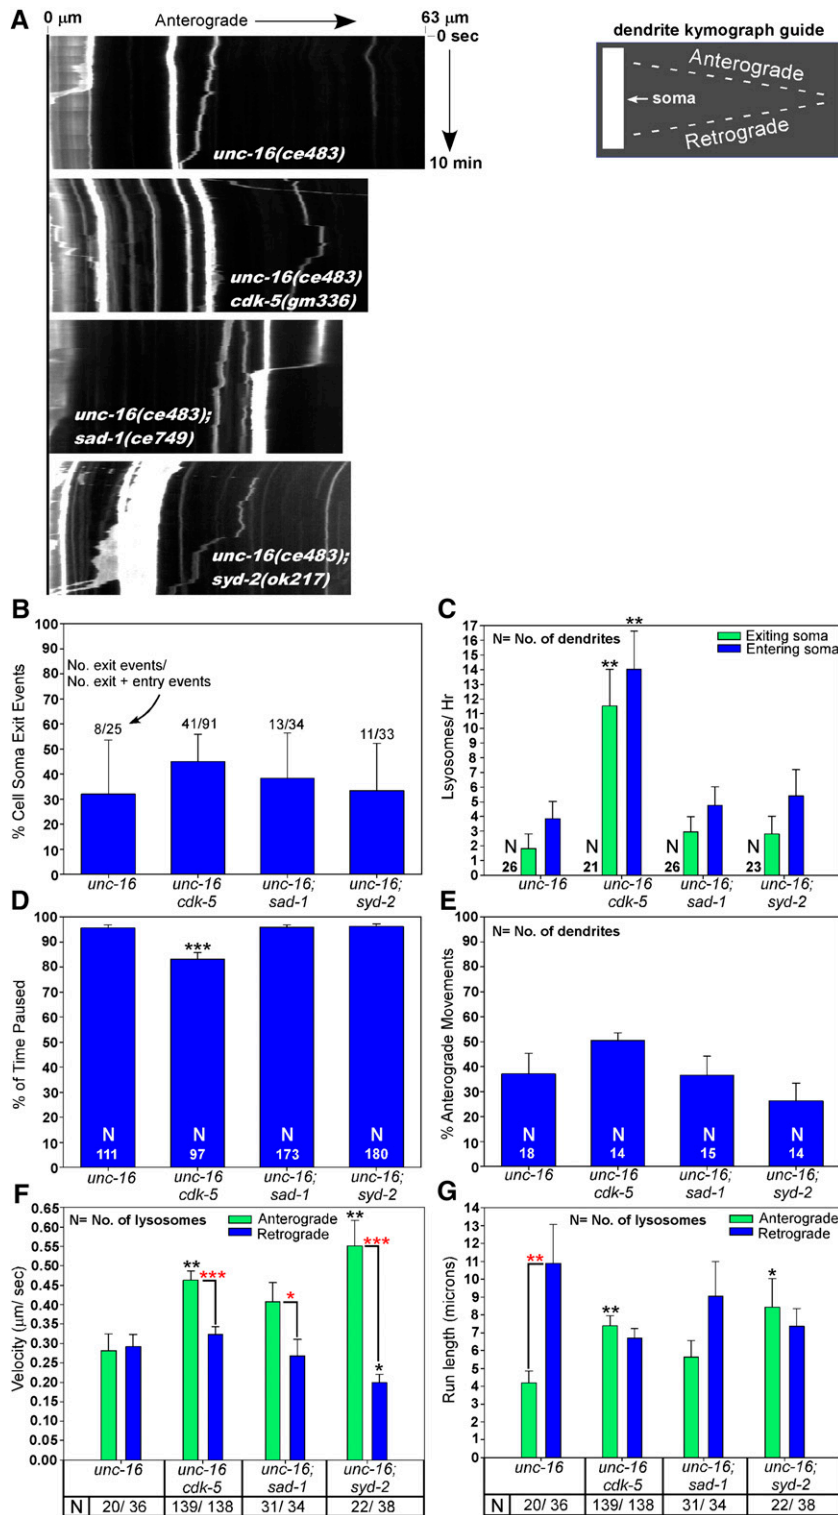

Figure 6 Regulation of dendritic lysosome transport by CDK-5, SAD-1, and SYD-2 in an *unc-16(+)* background. (A) Representative kymographs of CTNS-1-RFP-tagged lysosome movements in the DB7 dendrite of animals with the indicated genotypes. The bright region at the left of the top three images is the cell soma. CTNS-1-RFP is expressed from the integrated transgene *cels56*. See also movies in File S2, File S3, File S4, and File S5. (B–G) Graphs plotting various indicated parameters extracted from the kymographs and time-course analyses. Error bars in B are 95% confidence intervals derived from Fisher's exact test. All other error bars are standard errors of the means. *$P < 0.05$, **$P < 0.01$, and ***$P < 0.0001$. Black asterisks compare the marked bar to the wild-type value. Red asterisks compare the indicated two bars in a group. Unmarked bars are not significantly different from wild type or the other group member. Total recorded minutes used for exit/entry analyses (in order of strains as shown): 213, 356, 229, and 220. Total recorded minutes used for movement analyses (in order of strains as shown): 199, 311, 195, 207.

by the increased concentrations of dendritic lysosomes in the double mutants, which would tend to bias toward dendrite-to-soma entry events.

In *unc-16* single mutants the rate at which lysosomes exited the cell soma to the dendrite was ~20% of the wild-type rate ($P = 0.01$), although the rate at which lysosomes entered the cell soma from the dendrite was not significantly different from wild type. This is consistent with previous findings that lysosomes tend to move toward microtubule plus ends in *unc-16* single mutants and thus

Figure 7 Regulation of dendritic lysosome transport by CDK-5, SAD-1, and SYD-2 in an *unc-16(−)* background. (A) Representative kymographs of CTNS-1-RFP-tagged lysosome movements in the DB7 dendrite of animals with the indicated genotypes. CTNS-1-RFP is expressed from the integrated transgene *cels56*. Error bars in B are 95% confidence intervals derived from Fisher's exact test. All other error bars are standard errors of the means. Numbers at the base of the bars in D are the number of lysosomes analyzed. $*P < 0.05$, $**P < 0.01$, and $***P < 0.0001$. Black asterisks compare the marked bar to the wild-type value. Red asterisks compare the indicated two bars in a group. Unmarked bars are not significantly different from *unc-16(ce483)* or the other group member. Some statistical comparisons to the corresponding *unc-16(+)* strains (Figure 6) are stated in the text. Total recorded minutes used for exit/entry analyses (in order of strains as shown): 264, 214, 264, and 234. Total recorded minutes used for movement analyses (in order of strains as shown): 244, 128, 263, and 223.

accumulate in axons (Edwards *et al.* 2013). In *unc-16 cdk-5* double mutants, both the entry and exit rates were strongly and significantly increased compared to *unc-16* single mutants such that they were not significantly different from the wild-type entry and exit rates (Figure 7B; compare to wild type in Figure 6B). However, the entry and exit rates of *unc-16; sad-1* and *unc-16; syd-2* double mutants were

not significantly different from *unc-16* single mutants (Figure 7B).

Upon entering the dendrite, lysosomes in *unc-16* single mutants spent a significantly higher percentage of their time in a paused state compared to wild type (95 *vs.* 42% for wild type). In *unc-16 cdk-5* doubles, lysosomes spent significantly less of their time in a paused state (80%) compared to

unc-16 single mutants. However, lysosomes in both *unc-16*; *sad-1* and *unc-16*; *syd-2* double mutants were not significantly different from *unc-16* single mutants in percentage of time spent paused.

Analyzing the directionality of lysosome movements within the dendrite revealed what appeared to be a lower percentage of movements in the anterograde (minus-end) direction in *unc-16* single mutants compared to wild type (38 *vs.* 53%), but this was not quite statistically significant (comparing Figure 6E and Figure 7E). None of the double mutants significantly differed from the *unc-16* single mutant in this parameter.

The high fraction of immobile dendritic puncta in the *unc-16(−)* background hindered our ability to acquire high numbers of moving puncta for velocity and run-length analyses; however, we were able to collect enough data to see significant and potentially insightful differences. When not in a paused state, lysosomes in *unc-16* single mutants had mean velocities of 0.28 μm/sec (in either direction), which is nearly identical to the mean retrograde velocity of wild type (compare Figure 6F and Figure 7F). However, unlike wild type, in which anterogradely moving lysosomes had mean velocities ~60% faster than retrogradely moving lysosomes (Figure 6F), there was no significant difference in the mean retrograde and anterograde velocities of dendritic lysosomes in *unc-16* single mutants (Figure 7F). Consistent with having less resistance for anterograde movements and suppressing the *unc-16* null phenotype, all three double mutants had mean anterograde (minus-end-directed) velocities that were 43–96% higher than *unc-16* single mutants. Although this pattern was not quite statistically significant for the *unc-16*; *sad-1* double (P = 0.066), it was highly significant for the *unc-16 cdk-5* and *unc-16*; *syd-2* doubles, and lysosomes in all three doubles showed the wild-type pattern of moving significantly faster in the anterograde direction than in the retrograde direction. This phenotype was quite strong in the *unc-16*; *syd-2* double. This was the only one of the three doubles that had a mean retrograde velocity that was significantly slower than the *unc-16* single mutant, and its mean anterograde velocity was 275% higher than its mean retrograde velocity (Figure 7F).

Despite the fact that anterograde and retrograde velocities were not significantly different in *unc-16* single mutants, retrograde (plus-end-directed) run lengths in these dendrites were almost three times longer than anterograde run lengths in *unc-16* single mutants (Figure 7G). This is consistent with previous findings that lysosomes tend to move toward microtubule plus ends in *unc-16* single mutants and thus accumulate in axons (Edwards *et al.* 2013), where microtubules are oriented with their plus ends out (Goodwin *et al.* 2012; Yan *et al.* 2013). Consistent with having less resistance for anterograde movements and suppressing the *unc-16* null phenotype, two of the three double mutants (*unc-16 cdk-5* and *unc-16*; *syd-2*) had anterograde run lengths that were significantly longer than *unc-16* single mutants, and unlike *unc-16* single mutants, all three double

mutants showed no significant difference between antero-grade and retrograde run lengths when compared in the same strain (Figure 7G).

In summary, several of the lysosome active transport phenotypes in the double mutants would be expected to promote dendritic lysosome accumulation. In the *unc-16 cdk-5* double, the strongly increased rate at which lysosomes flux in and out of the soma (compared to *unc-16* single mutants), combined with spending 80% of their time in a paused state while in the dendrite, would promote dendritic trapping and accumulation of lysosomes, as would the increased anterograde (minus-end-directed) velocity and run lengths in the same strain. Similarly, although lysosomes in the *unc-16*; *sad-1* and *unc-16*; *syd-2* doubles do not differ significantly in their soma-dendrite flux rates compared to the *unc-16* single, they spend >95% of their time in a paused state upon entering the dendrite. In addition, like the *unc-16 cdk-5* double, their anterograde (minus-end-directed) movements within the dendrite are faster and longer than the *unc-16* single mutant (strongest in the *unc-16*; *syd-2* double).

Synapse assembly proteins also regulate the transport of early endosomes in neurons

In a prior study we found that, in addition to lysosomes, *unc-16* null mutants also accumulate similarly high levels of early endosomes in their axons (Edwards *et al.* 2013). To determine the extent to which CDK-5, SAD-1, and SYD-2 regulate early endosome transport in neurons, we crossed the *ceIs259* genomically integrated transgene into *cdk-5*, *sad-1*, and *syd-2* null mutants in *unc-16(+)* and *unc-16(−)* backgrounds. *ceIs259* expresses RFP-SYN-13 at a low level in the same motor neurons as the CTNS-1-RFP marker that we used for the lysosome studies. SYN-13 localizes to early/recycling endosomes (Prekeris *et al.* 1998; Chun *et al.* 2008) and was previously shown to precisely colocalize with YFP-RAB-5, another early endosome marker (Edwards *et al.* 2013). Because, unlike lysosomes, the endosomal puncta were often not well separated from each other, we quantified total integrated fluorescence/μm of axon or dendrite length in DA6/DB6 motor neurons and did not additionally quantify punctal density (Figure 8A shows the regions imaged).

In axons in an *unc-16(+)* background, wild type had very low, barely detectable levels of the early endosomes, but this level increased ~10-fold in an *unc-16(−)* background (Figure 8B). Thus, UNC-16 normally inhibits the accumulation of early endosomes in axons. None of the three single mutants differed significantly from wild type in their axonal early endosome levels; however, in an *unc-16(−)* background, all three double mutants had significantly reduced levels of axonal early endosomes relative to *unc-16* single mutants (38–50% of *unc-16*; Figure 8B), which was similar to, or slightly greater than, the total fluorescence μm reductions that we observed for lysosomes in the same genetic backgrounds (Figure 2C). Thus, UNC-16's activity in inhibiting the axonal accumulation of early endosomes is 50–62%
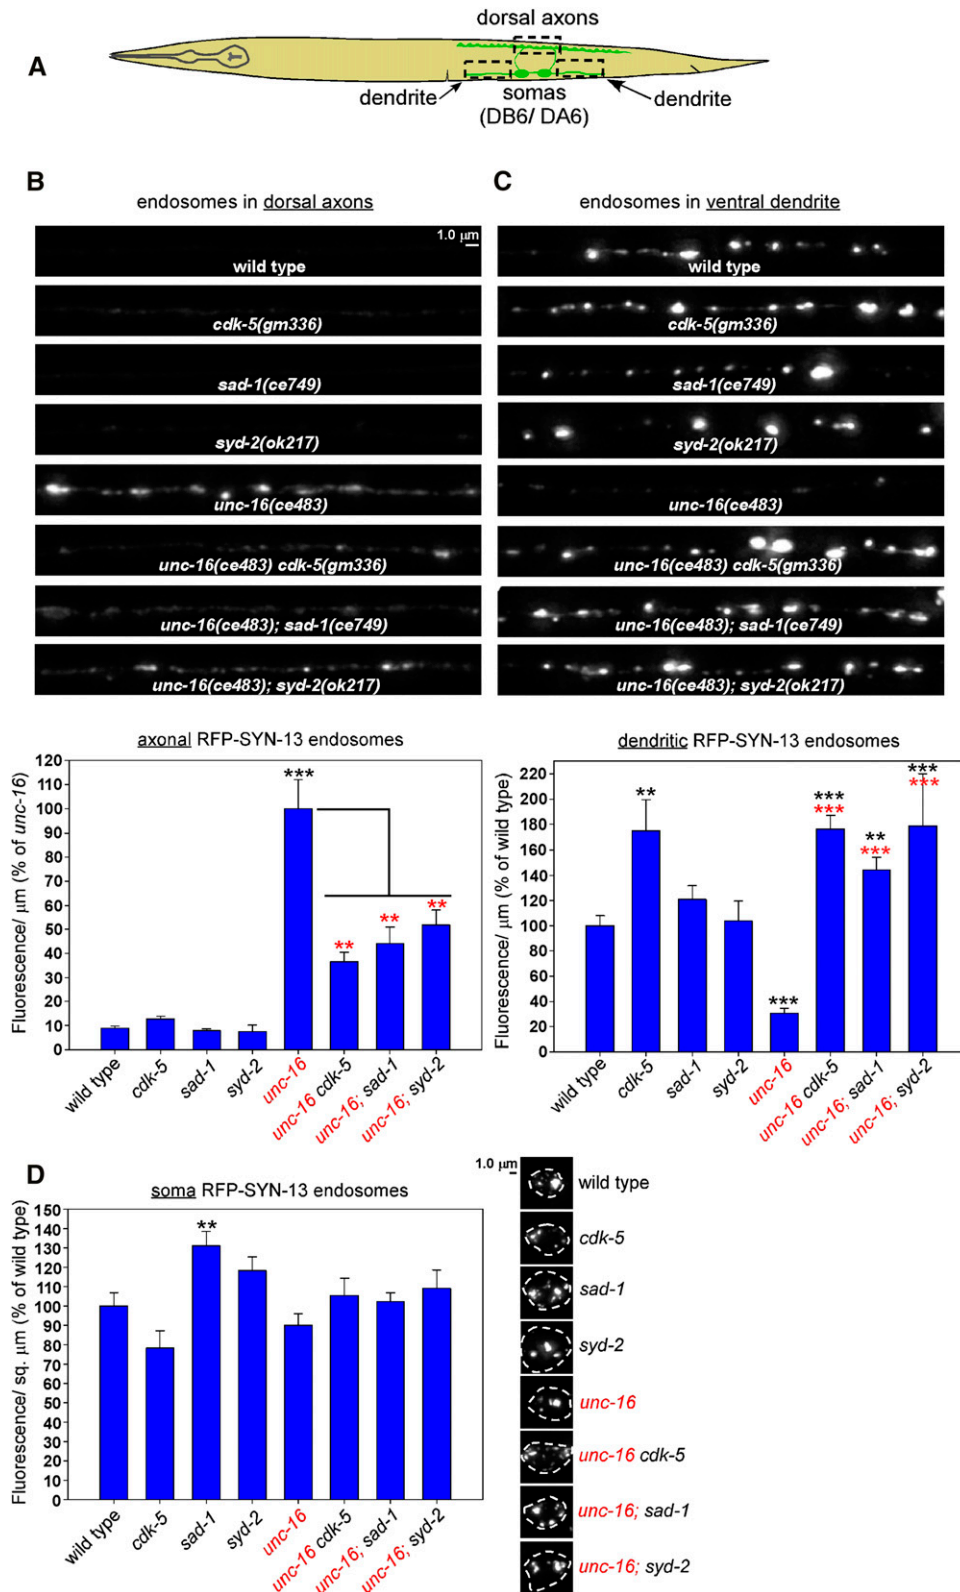

Figure 8 CDK-5, SAD-1, and SYD-2 regulate the distribution of endosomes in *unc-16* mutant neurons. (A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed box outlines regions imaged (both dendrite regions were collected and quantified together). (B–D) Representative, identically scaled images and quantification of RFP-SYN-13 endosomes expressed from the integrated transgene array *cels259* in the indicated genotypes in dorsal axons (B), ventral dendrites (C), or cell somas (D). Data are means and SEMs from 13–14 animals per region. **$P < 0.01$ and ***$P < 0.0001$. Black asterisks compare the marked bar with the wild-type value. Red asterisks compare the marked bar with the *unc-16* single-mutant value. Unmarked bars do not differ significantly from wild type.

dependent on the individual activities of CDK-5, SAD-1, and SYD-2.

In dendrites in an *unc-16(+)* background, wild type had a relatively high endosomal density, in contrast to the rela-

tively low levels of lysosomes in wild-type motor neuron dendrites (compare representative images in Figure 3B and Figure 8C). Unlike lysosomes, which showed a two-fold increase in *unc-16* mutant dendrites, the early endosome

level in *unc-16* single-mutant dendrites significantly decreased to ∼30% of wild type, consistent with the heavy endosome accumulation in *unc-16* mutant axons. Thus, UNC-16 normally promotes the accumulation of early endosomes in dendrites. In *cdk-5* single mutants, dendritic early endosome levels were significantly increased by ∼1.75-fold over wild type (similar to the fold-increase of lysosomes in the same mutant as shown in Figure 3B), but this level was not further increased in an *unc-16(−)* background (Figure 8C). In *sad-1* and *syd-2* single mutants, dendritic early endosome levels were not significantly different from wild type. However, even though *unc-16* single mutants had low early endosomes levels that were just 30% of wild type, the *unc-16*; *sad-1* and *unc-16*; *syd-2* doubles were either not significantly different (*unc-16*; *sad-1*) or ∼1.8-fold higher (*unc-16*; *syd-2*; *P* = 0.001) than the corresponding single mutants (Figure 8C). Thus, in dendrites, the *cdk-5*, *sad-1*, and *syd-2* null mutant early endosome distribution phenotype (high, similar to wild type) was completely epistatic to *unc-16*'s early endosome distribution phenotype (low/∼30% of wild type). This suggests that UNC-16's activity in promoting the dendritic accumulation of early endosomes is completely dependent on the individual activities of CDK-5, SAD-1, and SYD-2.

In cell somas, none of the single- or double-mutant combinations differed significantly from wild type in their early endosome levels, with the exception of the *sad-1* single mutant, which had slightly (but significantly) higher levels of the marker (Figure 8D). Thus, any differences in the distribution of this marker in axons and dendrites are unlikely to be explained by changes in transgene expression.

In summary, these results suggest that UNC-16 has a strong role in inhibiting the trafficking of early endosomes in the direction of microtubule plus ends (the anterograde direction in axons) and/or in promoting movement toward microtubule minus ends (the anterograde direction in dendrites). In axonal trafficking, for the fluorescence/μm parameter of the early endosome marker, UNC-16's activity is ∼50–60% dependent on the individual activities of CDK-5, SAD-1, and SYD-2, whereas in dendritic trafficking, UNC-16's activity in promoting the dendritic localization of early endosomes appears completely dependent on the CDK-5/SAD-1/SYD-2 system.

Synapse assembly proteins are less important for Golgi transport in unc-16 mutant neurons

In a prior study we found that, in addition to lysosomes and early endosomes, *unc-16* null mutants also accumulate similarly high levels of Golgi in their axons (Edwards *et al.* 2013). To determine the extent to which CDK-5, SAD-1, and SYD-2 regulate Golgi transport in neurons, we crossed the *ceIs267* genomically integrated transgene into *cdk-5*, *sad-1*, and *syd-2* null mutants in *unc-16(+)* and *unc-16(−)* backgrounds. *ceIs267* expresses PST-2-GFP at a low level in the same motor neurons as the other markers that we have used in this study (Figure 9A). PST-2 is a *C. elegans* ortholog

of a Golgi-resident 3′-phosphoadenosine 5′-phosphosulfate transporter (Dejima *et al.* 2010). A previous study (Edwards *et al.* 2013) showed that PST-2-GFP colocalizes with AMAN-2 (α-Mannosidase II) to Golgi mini-stacks (the form that Golgi takes in invertebrates).

The axons of wild-type worms had very low (barely detectable) levels of the PST-2-GFP marker, but this level increased ∼20-fold in an *unc-16(−)* background (Figure 9B). None of the three single mutants differed significantly from wild type in their axonal PST-2-GFP levels. In an *unc-16(−)* background, however, all three double mutants had significantly reduced levels of axonal PST-2-GFP relative to *unc-16* single mutants, but the reductions amounted to 67–73% of the *unc-16* single mutant (Figure 9B), which are less significant reductions than the lysosome and early endosome reductions.

The dendrites of wild-type worms had low levels of Golgi, but this level increased significantly by ∼4.5-fold in the *unc-16* single mutant (Figure 9C). None of the three single mutants (*cdk-5*, *sad-1*, or *syd-2*) differed significantly from wild type in their dendritic Golgi levels; and, similarly, none of the three double mutants with *unc-16* differed significantly from *unc-16* single mutants in their dendritic Golgi levels, although the *unc-16 cdk-5* and *unc-16*; *sad-1* doubles approached statistical significance for having levels that were ∼ two-fold higher than *unc-16* single mutants (Figure 9C; *P* = 0.08 and 0.054, respectively).

In cell somas, none of the single- or double-mutant combinations differed significantly from the control strains in their PST-2-GFP fluorescence/μm², with the exception of the *syd-2* single mutant, which had slightly (but significantly) higher levels of the marker (Figure 9D). Thus, the decreased levels of this marker in the double-mutant axons are unlikely to be explained by changes in transgene expression.

In summary, these results confirm previous findings that UNC-16 has a strong role in inhibiting the trafficking of Golgi to axons, but these new data show that this activity is only 27–33% dependent on the individual activities of CDK-5, SAD-1, or SYD-2, in contrast to the heavier dependence of lysosome and early endosome trafficking on these three proteins. To a lesser but significant extent, UNC-16 also inhibits the trafficking of Golgi to dendrites by a mechanism that does not require the individual activities of CDK-5, SAD-1, or SYD-2, nor does elimination of any one of these proteins in combination with UNC-16 significantly enhance the trafficking of Golgi to dendrites, in strong contrast with dendritic lysosome trafficking.

Discussion

In this study we used an unbiased forward genetic screen in *C. elegans* to discover a previously unknown system through which UNC-16 acts to regulate the active transport of lysosomes, early endosomes, and Golgi in neurons. The screen identified three conserved proteins as key regulators in this
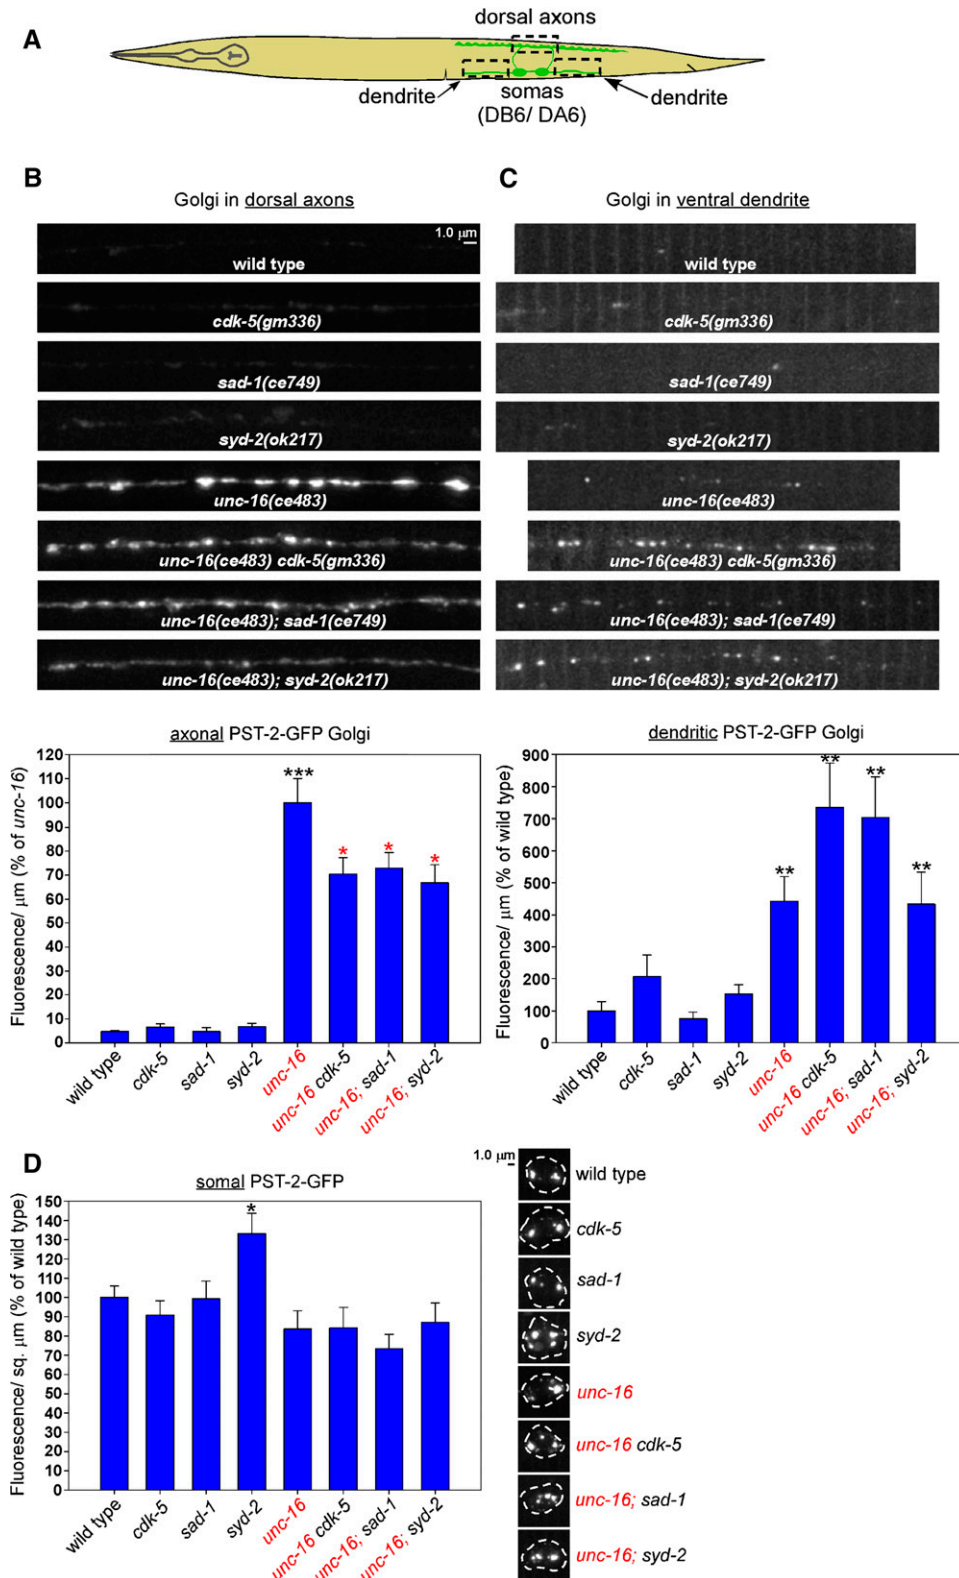

Figure 9 CDK-5, SAD-1, and SYD-2 regulate the distribution of Golgi in *unc-16* mutant neurons. (A) Drawing illustrates location and anatomy of the cholinergic motor neurons imaged in this figure. system: CDK-5, SAD-1, and SYD-2. Because the genetic results showed that the three proteins are all part of the same organelle transport regulatory system, we named it the CSS system based on the first letter of each founder protein. Further genetic analysis revealed important roles for the conserved proteins SYD-1 and STRD-1 in the CSS system. None of these proteins had previously been implicated in inhibiting the plus-end-directed transport of cell soma organelles to axons. Instead, previous studies have suggested that they that have highly specialized roles in

regulating synapse assembly (SYD-1, SYD-2, and SAD-1) and/or synaptic vesicle transport (CDK-5 and SYD-2). In an accompanying article in this issue, we provide evidence that SAD-1 and SYD-1 also regulate synaptic vesicle transport (Edwards *et al.* 2015). In the current study, we have combined the genetic strengths of *C. elegans* with quantitative imaging techniques and time-lapse imaging of lysosomes in motor neurons to gain insights into the roles of CDK-5, SAD-1, and SYD-2 in organelle transport and the extent to which their functions overlap or intersect.

The CSS system promotes axonal accumulation and inhibits dendritic accumulation of lysosomes in unc-16 null mutants

The results showed that the heavy accumulation of lysosomal puncta in *unc-16* mutant axons is 74–97% dependent on the individual activities of the CSS proteins, with CDK-5 having a significantly more important role than SAD-1 or SYD-2. Null mutations in all three of the genes reduced the total fluorescence/μm of the lysosomal marker by similar amounts, to ∼50% of the *unc-16* single mutant. The total fluorescence/μm includes both the puncta and a diffuse nonpunctal fluorescence from the lysosomal marker, the latter of which is also present in the *unc-16* single mutant. The source of the membrane(s) from which the diffuse fluorescence originates is unclear, but apparently its transport is regulated differently from the puncta in axons. In dendrites there was no such difference.

Because none of the individual CSS mutations completely suppressed the axonal accumulation of lysosomal puncta or total fluorescence of the lysosomal marker, we first hypothesized that the three proteins may be part of two or three different systems for regulating lysosomal transport in neurons. However, in our analysis of all possible combinations of double and triple mutants in *unc-16(+)* and *unc-16(−)* backgrounds we did not see significant additive effects of the mutations in either axons or dendrites, suggesting that all three proteins function within the same system. This does not mean that the proteins interact to mediate the same function nor that they operate in a single linear pathway. The genetic results are also consistent with the CSS proteins mediating two or more parallel but interdependent functions that ultimately converge to promote axonal accumulation and inhibit dendritic accumulation of lysosomes in *unc-16* null mutants. Consistent with this latter possibility, our time-lapse studies identified active transport phenotypes in both *unc-16(+)* and *unc-16(−)* backgrounds where *cdk-5* mutants differed from *sad-1* and *syd-2* mutants, although most active transport phenotypes were shared between the three mutants.

Other players

Our genetic screen was clearly not saturating: even though we found five *sad-1* alleles, we only isolated one allele each of *cdk-5* and *syd-2*. This suggests that further rounds of screening will identify other important players within this system. However, for this study, we began by testing null mutants that eliminate the functions of proteins known to interact with one or more of the CSS proteins. This complementary reverse genetics approach was fruitful, resulting in the identification of SYD-1 and STRD-1 (STRADα) as important determinants of lysosome distribution in *unc-16* mutant neurons. In addition, our results suggest that PCT-1 has a minor role in this system in both axons and dendrites, although CDK-5 appears mostly able to substitute for lack of PCT-1 in this context. NAB-1 (Neurabin) also appears to have a minor role, although only in *unc-16* mutant dendrites.

Synapse assembly proteins as general regulators of active transport in neurons

Several of the CSS proteins and "other players" noted above have been found to be important for synapse assembly and stability. For example SYD-2, SYD-1, SAD-1, and NAB-1 regulate synapse assembly and positioning of active zone components in *C. elegans* HSN neurons (Dai *et al.* 2006; Patel *et al.* 2006; Chia *et al.* 2012; Li *et al.* 2014). High-pressure freezing electron microscopy followed by tomographic reconstructions of active zones show that SYD-2 has roles in tethering/clustering synaptic vesicles near the active zone (Stigloher *et al.* 2011; Kittelmann *et al.* 2013) and in determining the size of the dense projection to which the synaptic vesicles are tethered (Kittelmann *et al.* 2013). In *syd-2* mutants, the rate at which synaptic vesicles dissociate from mature synapses is increased (Wu *et al.* 2013), and synaptic vesicles or clusters of vesicles accumulate in distal regions of the axon that are normally devoid of synapses and synaptic vesicles (Li *et al.* 2014; Edwards *et al.* 2015).

The phenotype of accumulation of synaptic vesicles in the distal asynaptic region of motor neurons, which could be considered diagnostic of reduced synaptic vesicle clustering activity at synapses, is also shared by *syd-1* and *sad-1* mutants (Li *et al.* 2014; Edwards *et al.* 2015), and prior studies also demonstrated defects in synaptic vesicle clustering at other synapses in *C. elegans sad-1* mutants (Crump *et al.* 2001; Patel *et al.* 2006). Other studies have proposed that *C. elegans sad-1* and *syd-1* mutants also have defects in axon identity/fate, referred to as a "polarity defect," based largely on the accumulation of synaptic vesicles in dendrites (Hallam *et al.* 2002; Hung *et al.* 2007; Kim *et al.* 2008, 2010). Indeed, SAD-1's orthologs do have roles in specifying axon identity in mammalian forebrain neurons (Kishi *et al.* 2005), where SAD-A/B act downstream of the LKB1 kinase (Barnes *et al.* 2007). However, neurons outside of the cortex, including peripheral motor neurons and many other types of central neurons, do not require the SAD kinases or LKB1 for axon formation/identity (Lilley *et al.* 2013). In the current study, we show that *sad-1* mutants have wild-type locomotion rates, a result that seems inconsistent with a motor neuron axon/dendrite identity defect.

In the accompanying article in this issue, we provide evidence that the accumulation of synaptic vesicles in *sad-1*,

syd-1, and *syd-2* motor neuron dendrites results from a defect in the regulation of synaptic vesicle transport, as opposed to an axon/dendrite identity defect (Edwards *et al.* 2015). Indeed, the regulation of synaptic vesicle and/or dense core vesicle transport appears to be another common theme that ties together several of CSS system proteins. Prior studies have also demonstrated a role for SYD-2 in synaptic vesicle and dense core vesicle transport in *Drosophila* (Miller *et al.* 2005) and *C. elegans* (Wagner *et al.* 2009; Goodwin and Juo 2013; Zheng *et al.* 2014), as well as for CDK-5 and PCT-1 in synaptic vesicle and dense core vesicle transport in *C. elegans* motor neurons (Ou *et al.* 2010; Goodwin *et al.* 2012).

Although Cdk5 has been shown to have a role in the active transport of acidic organelles in cultured cells (Pandey and Smith 2011), the current study is the first to show that several synapse assembly proteins (SYD-2, SYD-1, and SAD-1) also have general roles in regulating cell soma organelle transport in neurons. It is unclear whether there is a common mechanism that ties together the synapse assemble and active transport functions of SYD-1, SYD-2, and SAD-1 or whether they are simply hyper-adaptable to different functions. For example, SYD-2 belongs to a class of "intrinsically unstructured proteins" that can bind several partners in a structurally adaptive process (Wagner *et al.* 2009).

It is worth noting that SAD-1 and its mammalian orthologs also regulate axon termination (Crump *et al.* 2001) and terminal branching (Lilley *et al.* 2013) in certain classes of sensory neurons, and it is possible that this latter function might be related to the cell soma organelle transport function of SAD-1, since it would be reasonable to expect that organelle delivery, or lack thereof, could affect the length and branching of the axon. UNC-16 (JIP3) is also known to regulate axon elongation and branching as well as axonal transport and regeneration after injury (Cavalli *et al.* 2005; Bilimoria *et al.* 2010; Suzuki *et al.* 2010; Sun *et al.* 2013; Nix *et al.* 2014; Watt *et al.* 2015). However, it is unknown whether these axon growth functions of SAD-1 and UNC-16 are related and whether other CSS system proteins also participate.

Dynein redistributes lysosomes in unc-16 mutants when the function of the CSS system is blocked

We have not yet identified the plus-end-directed motor that carries organelles to axons in *unc-16* null mutants, although we have ruled out UNC-116 (Kinesin-1) (Edwards *et al.* 2013) and UNC-104 (KIF1A; this study). However, our data show that the loss of lysosomes from the axons of *unc-16 cdk-5* and *unc-16*; *syd-2* double mutants, as well as the accumulation of lysosomes in the dendrites of the same mutants, is dependent on NUD-2 (NUDEL/Nde1), a regulator of the minus-end motor dynein (Niethammer *et al.* 2000; Sasaki *et al.* 2000; Pandey and Smith 2011). In axons, crossing in the *nud-2* mutation completely suppressed the *unc-16*; *syd-2* phenotype back to the state of an *unc-16* single

mutant. In dendrites, crossing in the *nud-2* mutation completely suppressed the *unc-16*; *cdk-5* phenotype (heavy accumulation of lysosomes) back to the state of the *unc-16* single mutant. In the other two cases (*unc-16*; *cdk-5* axons and *unc-16*; *syd-2* dendrites), the suppression was nearly complete (60–78% of the *unc-16* single mutant). Our data are consistent with previous results showing that the accumulation of synaptic vesicles and dense core vesicles in *cdk-5* mutant dendrites is completely dependent on dynein and/or NUD-2 (Ou *et al.* 2010; Goodwin *et al.* 2012), and the accumulation of dense core vesicles in *syd-2* mutant dendrites is also completely dependent on dynein (Goodwin and Juo 2013). These epistatic or near-epistatic results seem consistent with a model in which the CSS system normally functions upstream of dynein and inhibits dynein (Figure 10). Thus, in an *unc-16* null single mutant, dynein would be inhibited by the CSS system, and the unidentified plus-end motor would carry lysosomes to axons. Genetically blocking the activity of the CSS system in an *unc-16* null mutant would then cause dynein to become overactive and bias movements toward the minus ends of microtubules, which would deplete organelles from axons and cause them to accumulate in dendrites (Figure 10). However, we are cautious to not overinterpret the epistatic suppression by the *nud-2* mutation since this result is equally consistent with a model in which the normal function of the CSS system is to positively regulate a plus-end motor or to regulate both motors. For example, a mutation in the plus-end motor UNC-104 (KIF1A) causes a 50% depletion of synaptic vesicles in axons and a corresponding 15-fold increase in dendritic synaptic vesicles, and yet crossing in the *nud-2* mutation epistatically redistributes synaptic vesicles to the wild-type state as well as restores wild-type locomotion (Edwards *et al.* 2015). By analogy, blocking the CSS system could decrease activity of the plus-end motor, thus allowing dynein-mediated minus-end movements to dominate and giving the appearance of hyperactive dynein, when in fact its activity could be unchanged. Indeed, a prior study used a GFP-tagged dynein subunit and time-lapse microscopy to look for hyperactive dynein in *cdk-5* mutant motor neuron dendrites in *C. elegans* and found no such evidence (Goodwin *et al.* 2012).

A previous study found that UNC-16's N terminus can interact with the dynein light intermediate chain DLI-1 in the yeast two-hybrid system. Full-length UNC-16 did not interact with DLI-1, however, and UNC-16 and DLI-1 could not be co-immunoprecipitated when co-expressed in COS-7 cells (Arimoto *et al.* 2011). Still, a study in vertebrates found that the dynactin subunits p50 and p150 could be co-immunoprecipitated with UNC-16 (JIP3) from the sciatic nerve (Cavalli *et al.* 2005). A later study in zebrafish observed cotransport of lysosomes and UNC-16 and, based on a decrease in the proportion of dynein-light intermediate chain-positive lysosomes moving in the minus-end direction in Jip3 mutants, concluded that UNC-16 functions as an important adaptor that links lysosomes to the dynein motor
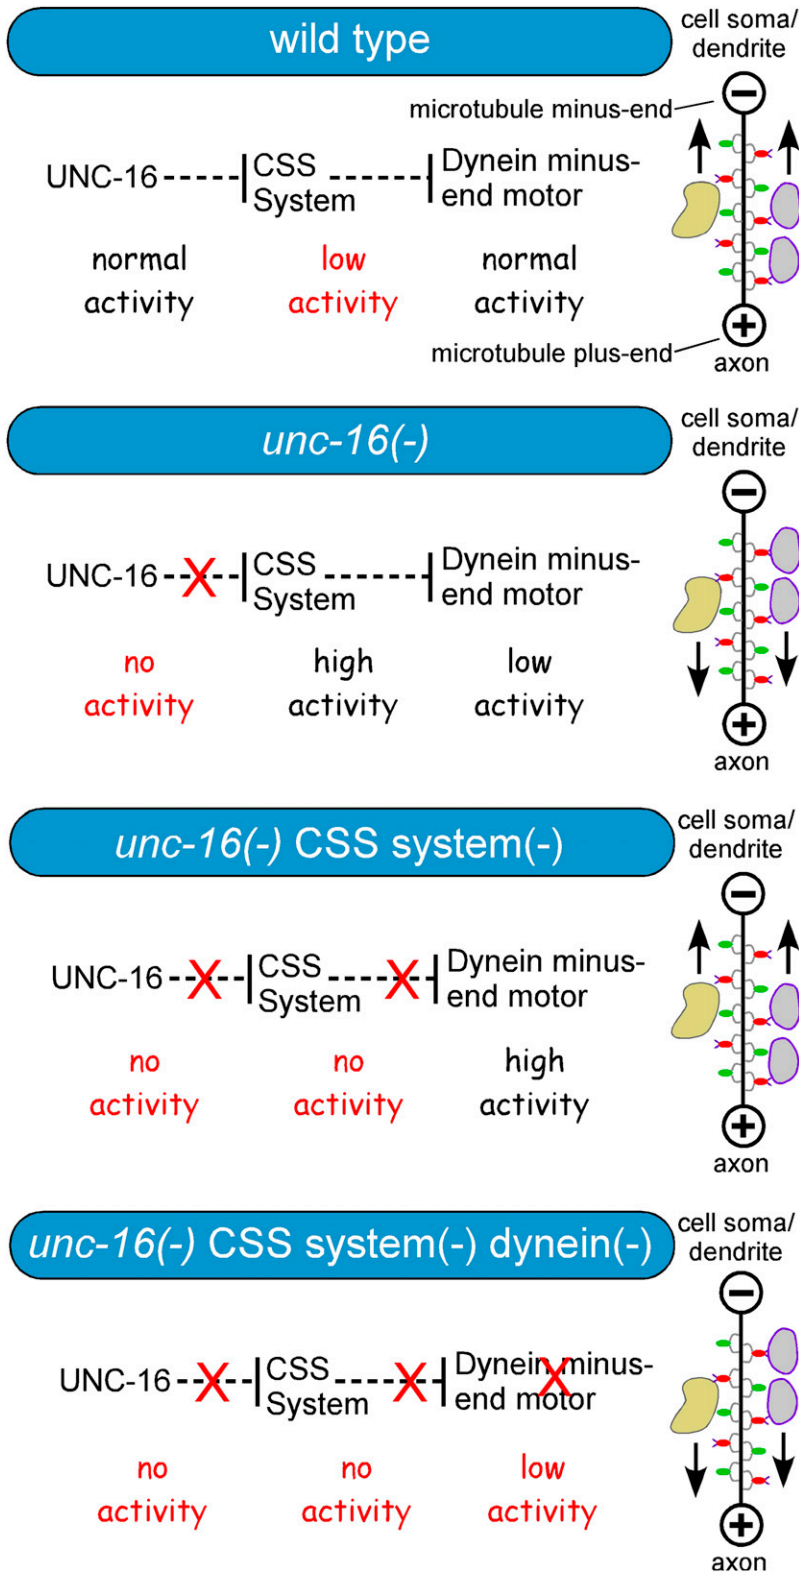

Figure 10 Graphic summary of genetic results. Shown is one possible model consistent with the genetic results. In wild-type animals, UNC-16 directly or indirectly inhibits the CSS system (vertical bars indicate inhibition). When CSS system activity is low, minus- and plus-end motor activity is properly balanced and cell soma organelles (lysosomes and endosomes; tan and purple shapes) remain in the soma and/or enter the dendrite at optimal rates. When CSS system activity is high, plus-end motor activity dominates due to inhibition of dynein, and organelles accumulate in axons. In other equally plausible models, the CSS system could positively regulate a plus-end motor or regulate both motors, and the effect on organelle transport would be the same.

through the dynein light intermediate chain (Drerup and Nechiporuk 2013). However, in that study, 63–85% of lysosomes (depending on the age of the animal) moving in the minus-end direction showed no cotransport with UNC-16. Thus, if UNC-16 also functions as an adaptor, it appears to not be required for linking most lysosomes to dynein. Our results do not exclude direct interactions between UNC-16 and dynein or dynactin. Such interactions could serve to localize UNC-16 to its sites of action. However, rather than viewing UNC-16 solely as an adaptor protein, our data seem

most consistent with a model in which one of UNC-16's functions is direct or indirect regulation of the CSS system proteins, which in turn regulate the minus- and/or plus-end-directed motors (Figure 10).

Active transport defects in CSS system mutants promote the dendritic accumulation of lysosomes

Given that our static imaging data showed that the lysosome levels in the dendrites of *sad-1* and *syd-2* single mutants do not differ significantly from wild type, and that the levels in *cdk-5* single mutants were only ~2.3-fold higher than wild type, we expected that time-lapse imaging of lysosomes in the dendrites of these mutants might not reveal any defects in active transport in an *unc-16(+)* background; however, this was not the case. All three mutants showed significant differences from wild type in at least two parameters for the active transport of lysosomes in dendrites. Our finding that dendritic lysosomes in all three mutants spend a higher percentage of their time in a paused state compared to wild type suggests that the CSS proteins are important for maintaining the processivity of lysosome movements. Dendritic lysosomes in all three mutants also had significantly slower minus-end-directed velocities when not in a paused state, although *sad-1* and *syd-2* mutants also had slower plus-end-directed velocities that resulted in shorter plus-end run lengths. Consistent with these data, prior studies in *C. elegans* reported that both *cdk-5* and *syd-2* null mutants have increased numbers of stationary dense core vesicles in their dendrites, and, additionally, dendritic dense core vesicles in *syd-2* null mutants have slower minus- and plus-end velocities (Goodwin *et al.* 2012; Goodwin and Juo 2013). The fact that we see significant effects of CSS mutations on dendritic lysosome transport in an *unc-16(+)* background shows that CSS proteins regulate the active transport of dendritic lysosomes even in wild type, and not just in an *unc-16(−)* background.

Our time-lapse analysis of dendritic lysosome movements in *unc-16* single mutants revealed several transport phenotypes that explain the bias toward plus-end transport that ultimately results in the accumulation of lysosomes in *unc-16* mutant axons. These include a strongly decreased rate of lysosomes exiting the soma to the dendrite (~20% of wild type), a possibly lower percentage of movements in the minus-end direction (not quite significant), a slower minus-end velocity than wild type (with no difference in plus-end velocity), and plus-end run lengths that were almost three times longer than minus-end run lengths. We also saw a two-fold increase in dendritic lysosomes in the *unc-16* single mutant. This minus-end accumulation seems counterintuitive, given the heavy plus-end accumulation in axons; however, it could result from the trapping of the few lysosomes that enter the dendrite. Trapping could result from the high percentage of time that dendritic lysosomes spend in a paused state in the *unc-16* single mutant (~95%).

Given the heavy accumulation of lysosomes in the dendrites of CSS mutants in an *unc-16(−)* background, we expected to see an increased rate of soma-to-dendrite exit events in all of the double mutants relative to the *unc-16* single mutant. That prediction, however, proved to be true only for the *unc-16 cdk-5* double, which had a soma-to-dendrite exit rate not significantly different from wild type (*i.e.*, about five times higher than the *unc-16* single mutant). Since soma-to-dendrite exiting is a minus-end-directed activity, this result is consistent with the strong *nud-2* suppression of dendritic accumulation of lysosomes in the *unc-16 cdk-5*; *nud-2* triple. However, this strongly increased exit rate is balanced by a corresponding increase in the soma-to-dendrite entry rate to a level not significantly different from either its exit rate or that of wild type. Thus, looking at entry and exit rates alone, there is no reason to predict that lysosomes should accumulate in *unc-16 cdk-5* mutant dendrites since they should be no different from wild type. Instead, the accumulation does occur, and the data suggest that it results from trapping of lysosomes in the dendrite due to the high percentage of time they spend in a paused state once entering the dendrite (~80 *vs.* ~40% for wild type), combined with increased minus-end velocities and longer minus-end run lengths compared to *unc-16* single mutants.

In contrast to the *unc-16 cdk-5* double, the *unc-16*; *sad-1* and *unc-16*; *syd-2* doubles were not significantly different from the *unc-16* single in their soma-to-dendrite flux rates in either direction. Although they spent a higher percentage of their time in a paused state than the *unc-16 cdk-5* double (95 *vs.* 80%), this was not different from *unc-16* single mutants. Thus, based on the soma-dendrite flux and pause parameters, there is no reason to predict that lysosomes should accumulate in the dendrites of these double mutants at levels any higher than the *unc-16* single mutant (approximately two-fold). However, consistent with the strong *nud-2* suppression of dendritic accumulation of lysosomes in the *unc-16*; *syd-2*; *nud-2* triple, both double mutants (*unc-16*; *sad-1* and *unc-16*; *syd-2*) had higher minus-end velocities and longer minus-end run lengths, similar to *unc-16 cdk-5* double mutants. We thus hypothesize that these minus-end-directed biases, combined with the high percentage of time spent in a paused state, leads to trapping and accumulation of lysosomes in the dendrites of *unc-16*; *sad-1* and *unc-16*; *syd-2* double mutants.

CSS system also regulates early endosome distribution in unc-16 mutant neurons but is less important for Golgi

A previous study in zebrafish proposed that UNC-16's organelle transport function is specifically limited to lysosomes, because late endosomes and autophagosomes did not appear to accumulate in zebrafish axons lacking UNC-16 (JIP3) (Drerup and Nechiporuk 2013). However, that study did not test early endosomes or Golgi membranes. In addition to lysosomes, *C. elegans unc-16* mutants also accumulate high levels of early endosomes and Golgi in their axons (Edwards *et al.* 2013). In this study, we found that the CSS system mediates the axonal accumulation of early endosomes

in *unc-16* null mutants to about the same extent that it mediates the axonal accumulation of lysosomes in *unc-16* null mutants (~50–60%, when using fluorescence/μm as the parameter). However, the 20-fold accumulation of Golgi in *unc-16* mutant axons was significantly less dependent on the CSS system (~30%). This suggests that the active transport of Golgi ministacks shares some, but not all, of the regulatory features of lysosomes and early endosomes.

Our analysis of early endosome and Golgi distributions in dendrites further emphasized this point and revealed additional regulatory differences between lysosomes and early endosomes. In contrast to lysosomes, early endosomes were relatively abundant in wild-type motor neuron dendrites, but were decreased four-fold in *unc-16* mutant dendrites, which is consistent with increased plus-end movement of early endosomes into axons. This suggests that UNC-16 normally promotes the minus-end transport of early endosomes to dendrites, just as we hypothesize it does for lysosomes (Figure 10). However, lysosomes are increased approximately two-fold over wild type in *unc-16* mutant dendrites. Based on our time-lapse data, we hypothesize that this increase results from rare lysosomes that enter the dendrite and become trapped in a paused state. Although we have not yet performed time-lapse imaging of early endosomes in *unc-16* null mutants, we hypothesize that they may be less susceptible than lysosomes to pausing and thus not as vulnerable to becoming trapped in the dendrite.

Just as with lysosomes, *cdk-5* single mutants were the only mutants that showed significantly elevated levels of early endosomes in dendrites in an *unc-16(+)* background. In dendrites, the *cdk-5*, *sad-1*, and *syd-2* null mutant early endosome distribution phenotype (high, similar to wild type) was completely epistatic to *unc-16*'s early endosome distribution phenotype (low/~30% of wild type). Thus, in dendritic trafficking, UNC-16's activity in promoting the dendritic localization of early endosomes appears completely dependent on the CSS proteins, suggesting that UNC-16 directly or indirectly inhibits the CSS system to produce an appropriate ratio of plus- to minus-end motor activity that maintains early endosomes in the cell soma and/or the dendrite at optimal levels (Figure 10).

Unlike early endosomes, but similar to lysosomes, Golgi membranes are present only at very low levels in wild-type dendrites. Similar to lysosomes, the dendritic Golgi marker is increased in the *unc-16* single mutant (~4.5-fold over wild type). Although we have not yet performed time-lapse imaging of Golgi in *unc-16* null mutants, we hypothesize that, similar to lysosomes, this accumulation results from rare Golgi ministacks that enter the dendrite and become trapped due to a high rate of pausing in dendrites in an *unc-16(−)* background. However, in an *unc-16(−)* background, eliminating individual CSS system proteins did not significantly increase the dendritic levels of Golgi, although two of the three doubles (*unc-16 cdk-5* and *unc-16; syd-2*)

approached statistical significance for having ~2-fold higher levels than the *unc-16* single mutant. This again suggests that the active transport of Golgi ministacks is less regulated by the CSS system than lysosomes and early endosomes and thus shares some, but not all, of the regulatory features of lysosome and early endosome transport.

Conclusion

Using the strengths of the genetic model *C. elegans*, we have discovered a new, unprecedented, and counterintuitive role for synapse assembly proteins in regulating the transport of cell soma organelles in neurons, where they act downstream of the conserved protein UNC-16, as part of the newly defined CSS system. Key factors contributing to this discovery were an unbiased forward genetic screen, genetic tools and techniques that facilitated the construction of complex strains for analysis, and the ability to perform high-resolution, quantitative imaging of organelles in defined regions of identified motor neurons in live animals. Still, much remains to be learned about how UNC-16 interacts with the CSS system and how the CSS system in turn regulates minus- and/or plus-end motors. Notably, the relevant plus-end motor in this system remains unidentified. Future genetic studies, including new forward genetic screens, additional cycles of the current screen, and reverse genetic approaches, should identify the plus-end motor, as well as positive and negative regulators of this new system. Such studies should reveal general principles governing organelle transport in neurons and could provide important insights into motor neuron diseases that are associated with axonal transport defects.

CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. *ceEx450, ceEx472, and ceEx474* are transgenic extrachromosomal arrays that express the *cdk-5* cDNA, *sad-1a* cDNA, or *syd-2* gene in the same neurons as CTNS-1-RFP. Data are means and SEMs from 13-14 animals per region. *P<.01; **P<=.001; ***P<=.0001.
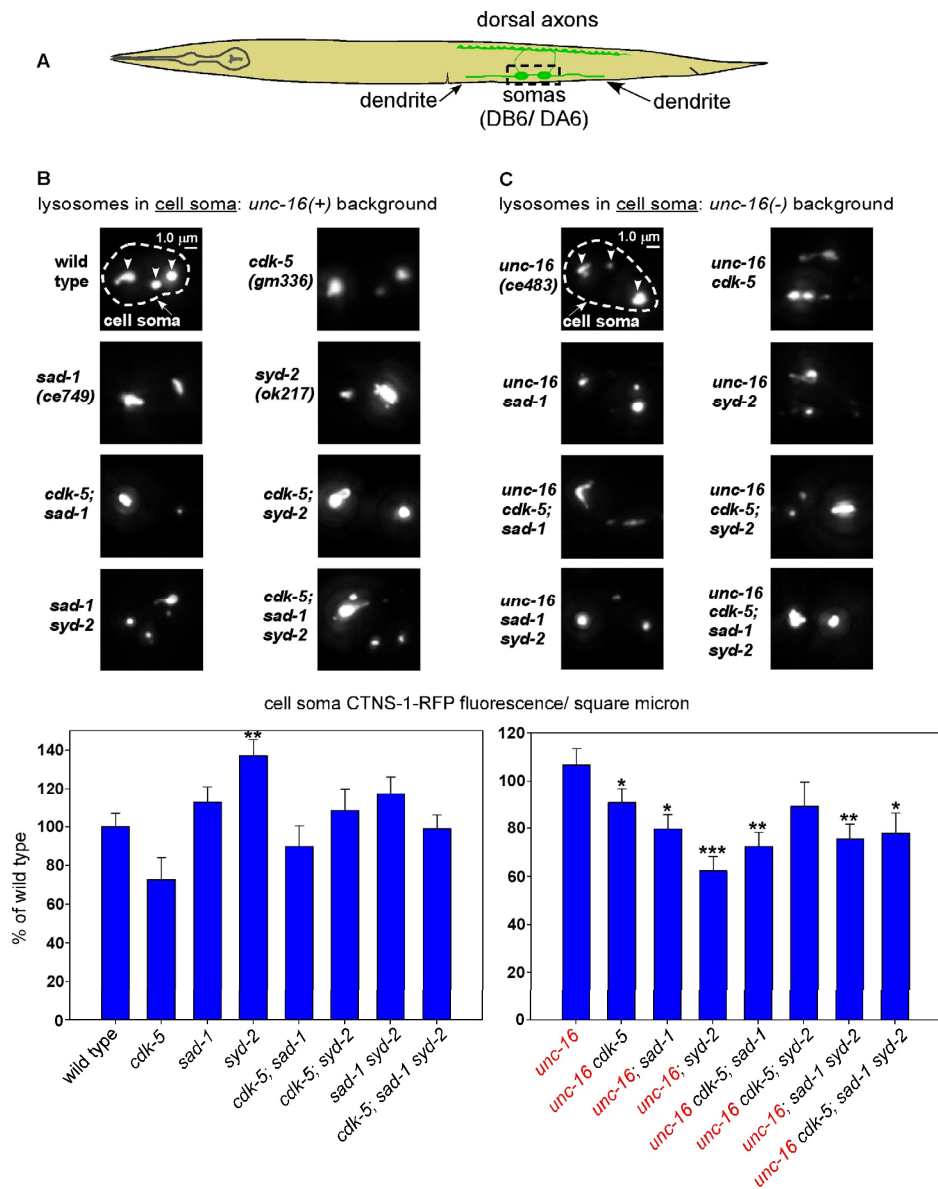

Figure S2. *cdk-5*, *sad-1*, and *syd-2* loss of function mutations are associated with mild to moderate decreases in CTNS-1-RFP cell soma levels in an *unc-16(-)* background.

(A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed box outlines the region imaged (both cell somas were imaged together and then combined for quantification).

(B and C) Representative, identically-scaled images and quantification of CTNS-1-RFP total fluorescence per square micron of the indicated genotypes in an *unc-16(+)* background **(B)** or an *unc-16(-)* background **(C)**. Dashed lines and arrowheads on the wild type and *unc-16* representative images indicate cell soma boundaries and CTNS-1-RFP – labeled lysosomes, respectively. CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. Data are means and SEMs from 13-14 animals. Asterisks indicate genotypes with values significantly different from wild type **(B)** or *unc-16(ce483)* **(C)** (*, P=.02 – .0075; **, P=.001 - .003; ***, P<0.0001). Unmarked bars are not significantly different from wild type **(B)** or *unc-16* **(C)**.
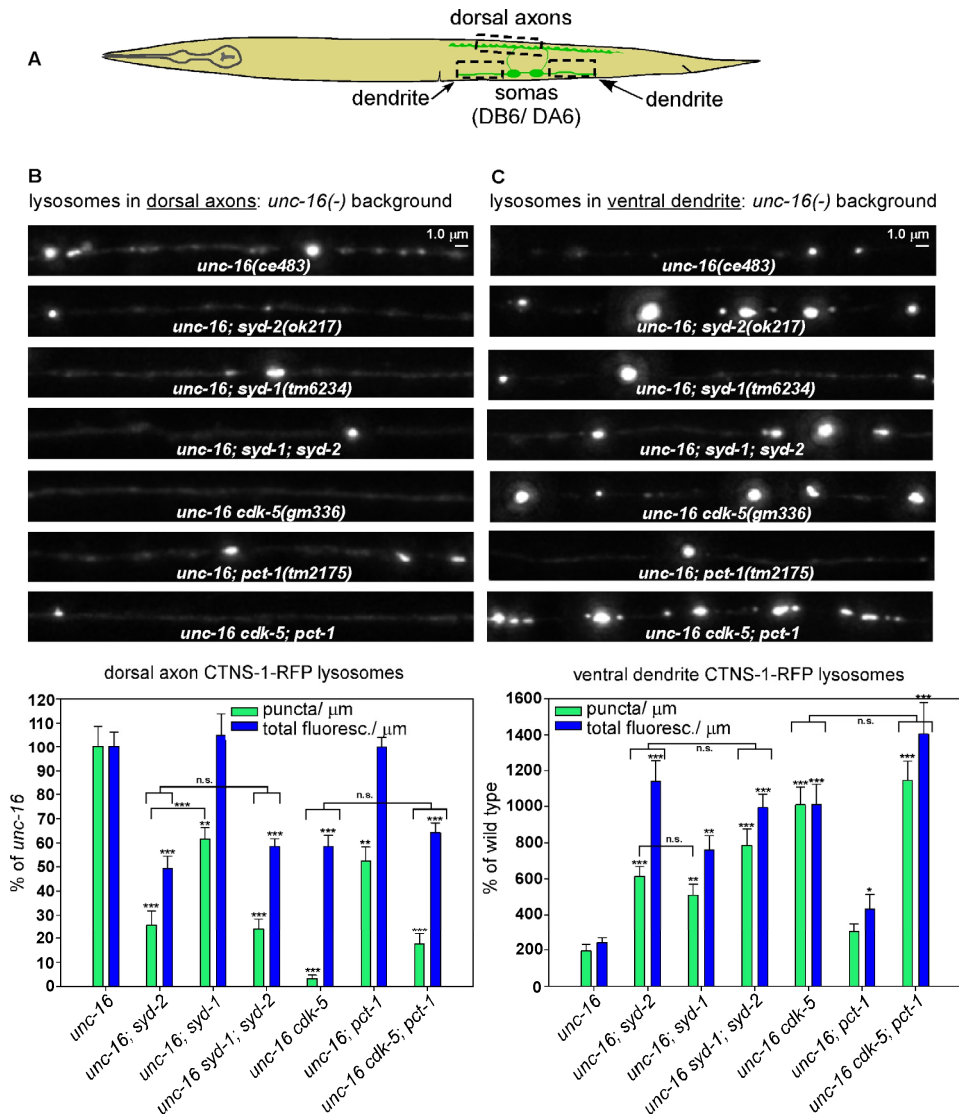

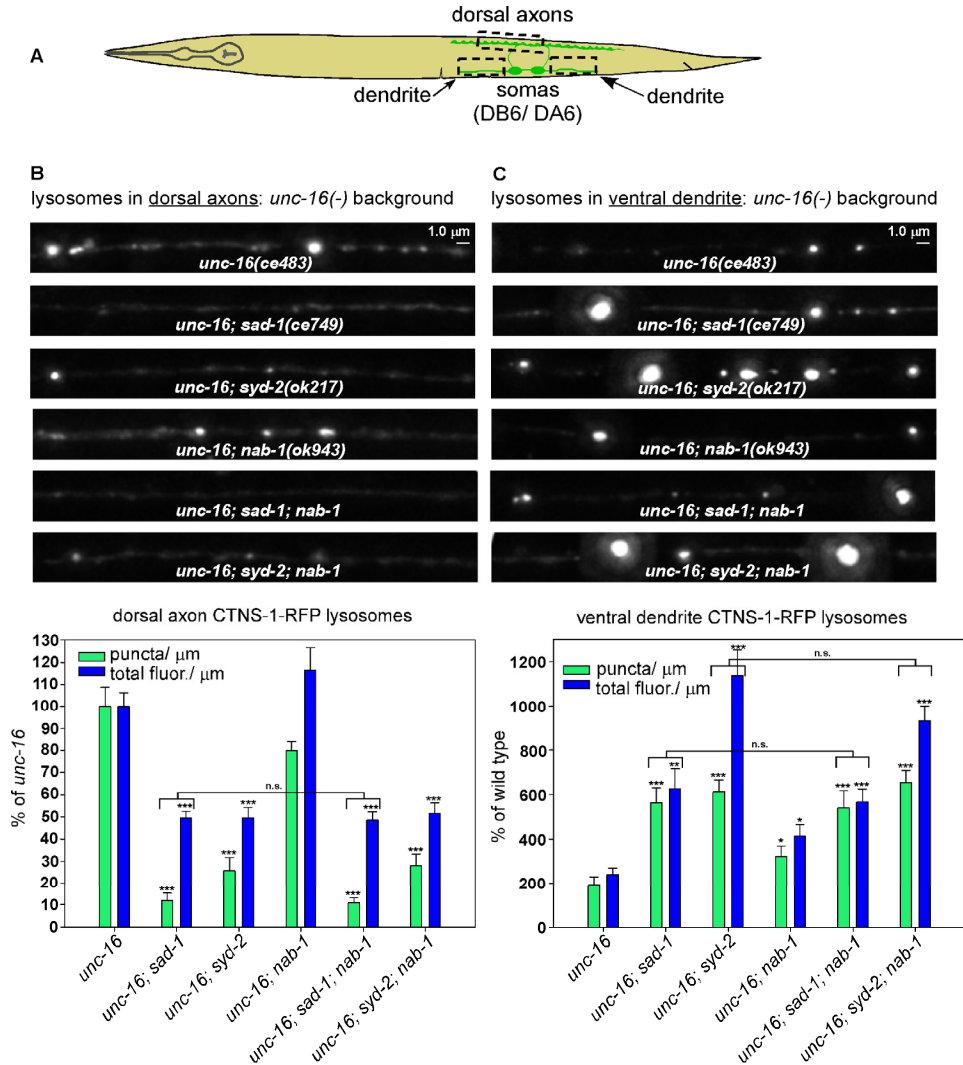

Figure S3. SYD-1 and SYD-2 act in the same pathway to regulate axonal and dendritic lysosome content; CDK-5 can mostly substitute for loss of PCT-1 (Pictaire kinase) but PCT-1 cannot substitute for loss of CDK-5.

(A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed boxes outline the regions imaged.
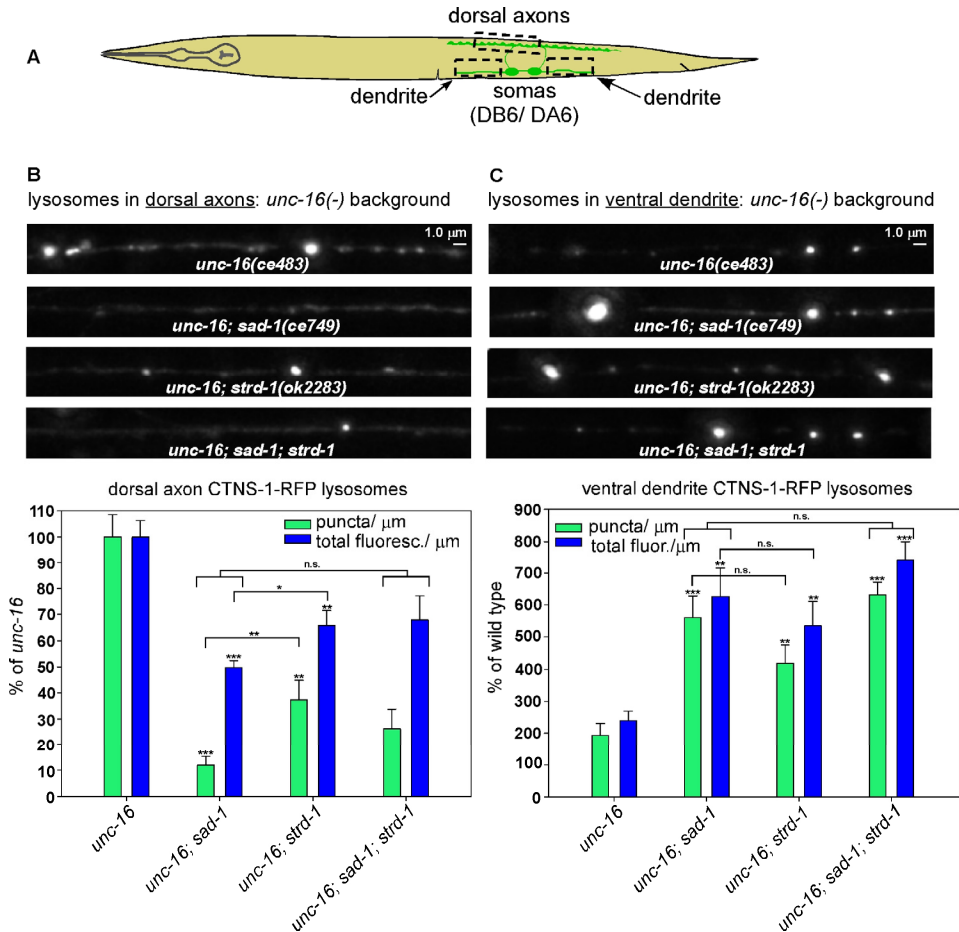

(B and C) Representative, identically-scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micron in the dorsal axons **(B)** and ventral dendrites **(C)** of the indicated genotypes. CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. Data are means and SEMs from 13-14 animals per region. Asterisks over bars indicate values significantly different from *unc-16*. Asterisks over brackets denote P values for the selected comparisons: *, P<.05; **, P<.01; ***, P<.0001; n.s., not significant.

Figure S4. NAB-1 is not required for axonal accumulation of lysosomes in *unc-16* mutants, but it has a minor role in regulating the dendritic accumulation of lysosomes in *unc-16* mutants, where it acts in the same pathway as SAD-1 and SYD-2.

(A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed boxes outline the regions imaged.

(B and C) Representative, identically-scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micron in the dorsal axons **(B)** and ventral dendrites **(C)** of the indicated genotypes. CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. Data are means and SEMs from 13-14 animals per region. Asterisks over bars indicate values significantly different from *unc-16*. Asterisks over brackets denote P values for the selected comparisons: *, P<.05; **, P<.01; ***, P<.0001; n.s., not significant.

Figure S5. The function of STRD-1 overlaps with SAD-1 to regulate the trafficking of lysosomes in axons and dendrites.

(A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed boxes outline the regions imaged.
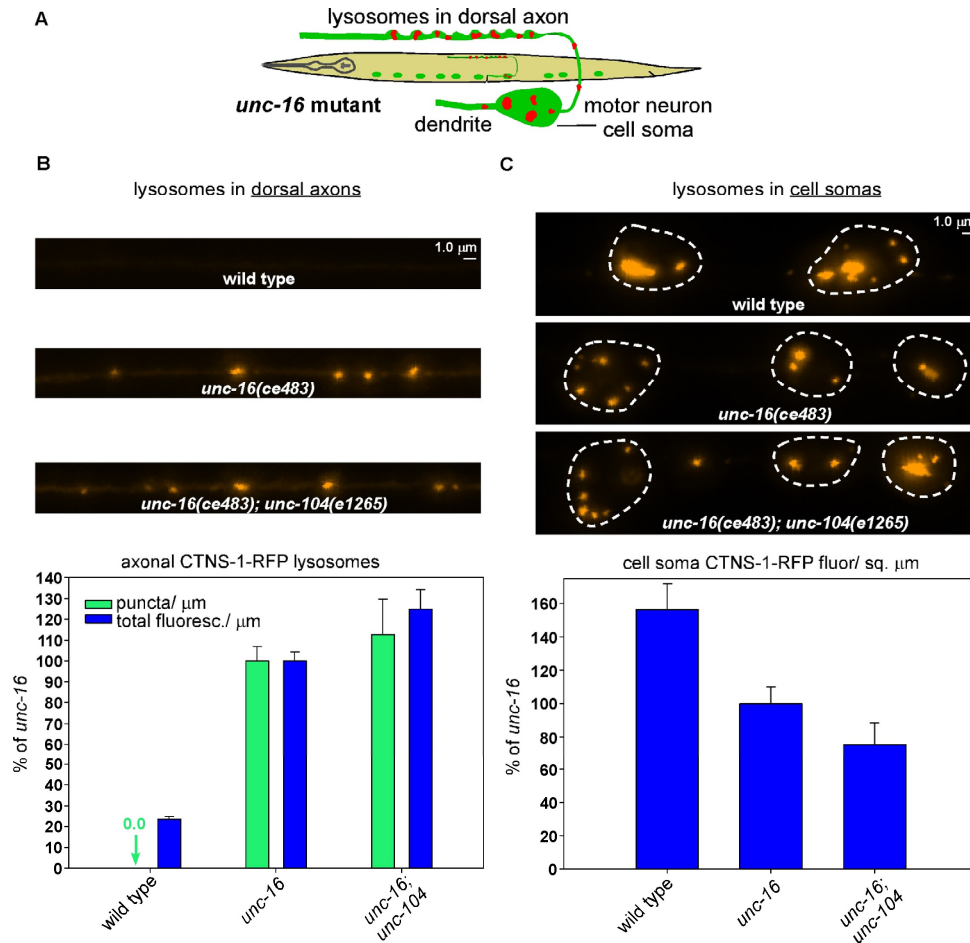

(B and C) Representative, identically-scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micron in the dorsal axons **(B)** and ventral dendrites **(C)** of the indicated genotypes. CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. Data are means and SEMs from 13-14 animals per region. Asterisks over bars indicate values significantly different from *unc-16*. Asterisks over brackets denote P values for the selected comparisons: *, P<.05; **, P<.01; ***, P<.0001; n.s., not significant.

Figure S6. KIF1A (UNC-104) is not the motor that carries lysosomes to the axonal synaptic region in *unc-16* mutants.

(A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure.

(B and C) Representative, identically-scaled images and quantification of CTNS-1-RFP lysosomal puncta and total fluorescence per micron in the dorsal axons **(B)** and ventral cell somas **(C)** of strains with the indicated genotypes. CTNS-1-RFP is expressed from the integrated transgene *ceIs134*. Data are means and SEMs from 13-14 animals per region. The *unc-16; unc-104* double mutant is not is not significantly different from the *unc-16* single mutant for axonal puncta/ μm or cell soma fluorescence/ sq. μm, but it has slightly more axonal total fluorescence/ μm (P=.03).
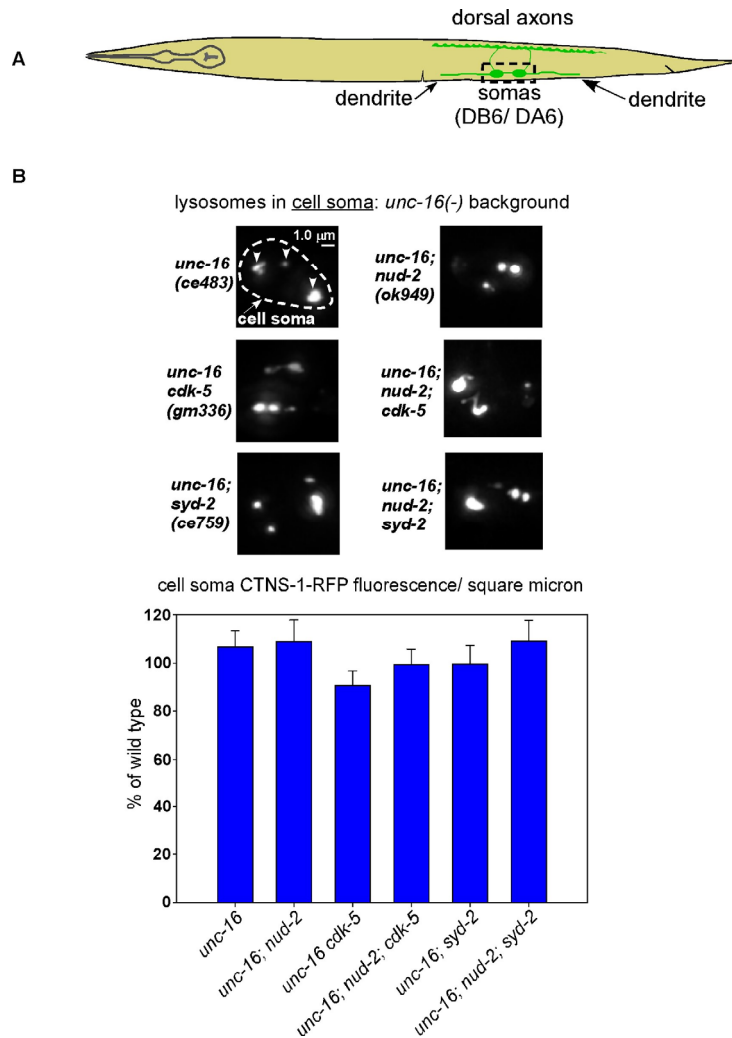

Figure S7. CTNS-1-RFP cell soma levels are not significantly affected in the strains used for the *nud-2* experiments.

(A) Drawing illustrates the location and anatomy of the cholinergic motor neurons imaged in this figure. Dashed box outlines the region imaged (both cell somas were imaged together and then combined for quantification).

(B and C) Representative, identically-scaled images and quantification of CTNS-1-RFP fluorescence per square micron of the indicated genotypes. Dashed lines and arrowheads on the wild type and *unc-16* representative images indicate cell soma boundaries and CTNS-1-RFP – labeled lysosomes, respectively. CTNS-1-RFP is expressed from the integrated transgene *ceIs56*. Data are means and SEMs from 13-14 animals. None of the double or triple mutant strains are significantly different from the *unc-16* single mutant.

File S1. Supplemental Materials and Methods, Strains, Plasmids, Transgenes, and Supporting Information References

Supplemental Materials and Methods

Quantitative fluorescence imaging of live animals and image analysis

Growth of Strains: For strains with wild type growth, we plated 12 L2-stage larvae on each of 5 locomotion plates and grew them 1 d at 14° + 5 at 20° (for growth and imaging at 20°) to produce next generation young adult progeny. Growth times and plating numbers were modified after growth tests for slow growing or lower fertility strains, such as strains containing *unc-104(ce782)* or *nud-2(ok949)*. ~55 - 65 young adults were selected and transferred to an unseeded plate immediately prior to mounting as described below.

Agarose pad slide production: We cleaned the glass slides before applying the agarose pad by placing sets of slides in slide staining dishes and shaking them for 30 min in dilute dishwasher soap followed by 1 min rinses in tap water and house distilled water, and 5 min rinses in 70% EtOH + 1% HCl and house distilled water followed by drying in a 60° oven. Cleaned slides were stored between layers of Kimwipes in a plastic container. We produced ~18-19 mm diameter 2% agarose pads using the method of (Sulston and Hodgkin 1988), with the agarose made in M9 buffer. We produced agarose pad slides in batches and stored them with the pads covered with a 24 x 30 mm coverslip to keep the surface smooth for up to 3-4 weeks in humidified containers at 4°.

Mounting animals on agarose pad slides: We transferred the pre-picked animals into a 30 µl drop of 30 mg/ ml BDM (2, 3-Butanedione monoxime; Sigma B0753) in M9 buffer in one pick-full and incubated them for 10 min on a water-moistened 1.5 cm square pad of folded Kimwipe tissue under a Petri plate lid. After the incubation, we removed ~27 µl of the solution using a P20 microinjection tip (Eppendorf 5242 956.003), leaving the worms behind in the remaining anesthetic and inverted the coverslip onto a ~18-19 mm diameter 2% agarose pad that had been dried without its protective coverslip for the final 4 min of the incubation. After straightening the coverslip slightly and nudging it ~1 mm to possibly help with dorsal/ ventral orientation, we sealed two diagonal corners with a dab of clear nail polish and imaged animals over the next 35 – 55 min.

Image Acquisition: We acquired images using a Nikon Eclipse Ti-E inverted microscope equipped with a Nikon CFI Apo TIRF 100X/ 1.49 N.A. objective, a Nikon motorized high resolution z-drive, and a motorized filter turret containing GFP, YFP, and Texas Red filter cubes (Semrock). Our illumination source was a SOLA Light Engine LED source (Lumencor). We acquired images with an ORCA Flash 4.0 16-bit camera (Hamamatsu, Bridgewater, NJ) controlled by Metamorph v. 7.7. We controlled exposure times by using Metamorph to turn the LEDs on and off rather than using a shutter. We only collected images from animals with their ventral or dorsal surfaces facing the objective. Z-series interval sizes (0.312 µm) and plane numbers (16) were the same for all strains and transgenes. Exposure times were as follows: *ceIs56* strains: 30 mSec, Texas Red filter; *ceIs259* strains: 10 mS, Texas Red filter; *ceIs267* strains: 85 mS, GFP filter. Because of the large field of view of the camera, we only collected the center quadrant of the camera's chip. The LEDs on the SOLA Light Engine were turned off via software control between successive planes. Before imaging each strain, we measured the light power of the peak emission wavelength at the objective using an XR2100 power meter (Lumen Dynamics) and an XP750 objective plane light sensor (Lumen Dynamics) with the stage position set at a standard distance (z-position) from the objective. We then adjusted the percent power of the SOLA Light Engine to produce the targeted mW power for the experiment. The percent power required to reach the target value varied by <=1% over the entire course of the experiment.

Processing Images: We used AutoDeblur Gold CWF (Media Cybernetics) to deconvolve the image stacks using the Adaptive PSF blind method and 10 iterations at the low noise setting. After deconvolving, we used Metamorph to make maximum intensity projections of each image stack.

Quantifying Images: We used Metamorph 7.7 for all analysis and quantification. To quantify fluorescence intensities per micron, we used the Trace Region tool to trace the region and used the Multiline tool to obtain the length of the traced region. We then copied and moved the region to a similar "on animal" background region for use in background subtraction. For dorsal axons, we traced the entire axon length across the image. To trace the dendrite regions around DA6 and DB6, we used the multi-line tool to trace 20 microns along the dendrite starting at one of the cell soma boundaries that faces the other cell soma. If the region between and including the two somas was >20 µm, we deleted these lines and started each of the two dendrite regions at the outer edge of each soma, proceeding outward to each edge of the image. If the region between and including the two somas was <=20 µm, we made a 2nd line that follows the dendrite in the opposite direction starting at the inner boundary of the other cell soma and proceeding in the opposite direction. If we came to the other cell soma before reaching 20 µm, we continued measuring across the soma to the dendrite on the other side of the soma until we reached 20 µm. We then started our dendrite traces at the end of each of these two lines, proceeding outward to each edge of the image using the Trace Region tool and combining the data from the two dendrite regions. Axonal and dendritic data were logged to a spreadsheet, which subtracted the background and computed the total fluorescence per micron of length. To quantify DA6 and DB6 cell soma intensity per square micron, we traced each soma separately and added them together, again using the traces to make "on animal" background regions for subtraction. To quantify puncta per micron, we set a minimum pixel intensity threshold after viewing a series of images collected from *unc-16* mutant dorsal axons. We then used the Threshold plug-in of Metamorph to highlight all pixels in the region that exceeded the threshold and counted the pixel clusters that exceeded this value, irrespective of the number of pixels in the cluster. We used the same threshold value in all strains throughout the experiment.

Producing Representative Images: After quantifying an image set we produced representative images for display by saving 8-bit versions of an image that was close to mean +/- standard error for the set. All representative images were scaled identically.

Time lapse video microscopy of organelle active transport in live animals

Growth of Strains: Animals were grown to the young adult stage as described above for quantitative fluorescence imaging, except we used as many as 30-40 locomotion plates to provide sufficient numbers of animals for the many time lapse mountings.

Agarose pad slide production: To avoid variability in agarose pad dryness, which affects animal compression and can affect active transport activity, we standardized a protocol for agarose pad slide production for time lapse imaging. After melting 0.2 g of agarose in

10 mls of M9 in a 50 ml glass bottle, we poured 0.5 ml of the molten agarose into several 1.5 ml microcentrifuge tubes in a 100° Isotemp block (Fisher). We inserted a blunt P200 pipet tip into each of 4 microcentrifuge tubes filled with distilled water and heated them to 100° in the Isotemp block. We preheated 8 clean slides (see above protocol for cleaning slides) along the front and back plastic surfaces of the Isotemp block outside of the metal tube holding blocks. We then arranged 4 pairs of spacer slides (slides with 1 layer of lab labeling tape + 1 layer of ¾ inch Scotch tape to raise them off the bench), tape side up, in front of the Isotemp block. To make the agarose pads, we placed one of the warm bottom slides between the first pair of spacer slides. We then moved one of the warm top slides to a Sardstedt Styrofoam block that is in front of the first pair of spacer slides such that the slide is in perpendicular orientation relative to the bottom slide. We removed the first hot blunt P200 tip from its hot water tube in the Isotemp block, shook it to get rid of excess water, and attached it to a P100 set on 50 μl. We then pipetted 50 μl from the open tube of molten agarose, lifting the tube out of the block briefly during pipetting. We began pipetting immediately when the tip touched the agarose, and then set the tube back in the block and pipetted the agarose onto the bottom slide between the spacers. After hovering the top slide over the agarose drop for ~1 sec, we then applied the top slide perpendicular to the bottom slide. The amount of pressure applied over the spacer slides depends on the how the drop spreads/ forms. The goal is for an average size pad to be 18-19 mm in diameter. After the 4 slides had been made, we pre-warmed another set of 8 slides and 4 blunt P200 tips for the next set. We then removed the top slide from the first slide pair and immediately applied a 24 X 30 mm coverslip to the agarose pad such that the long dimensions of the coverslip and slide are perpendicular to each other and the coverslip hangs off the edge of the slide, and then transferred this to a humidified plastic container. We repeated this with the remaining 3 slides, and then repeated this for another set of 4 slides if needed. Slides were stored at 4° until they were used the next day.

Mounting animals on slides: We first equilibrated the agarose pad slides at the intended temperature in their humidified container and prepared fresh 6 mM Levamisole in M9 from a powder stock of Levamisole (Acros Organics; AC187870100; <6 months old). To mount animals on a pad, we pre-picked 30-40 young adults to an unseeded plate, applied 30 μl of 6 mM levamisole to a 24 X 30 mm coverslip, picked the 30 young adults to the droplet in one pick-full, and incubated them for 6:10 min on a moist Kimwipe square under a Petri plate lid. Immediately after picking the worms to the drop, we removed the coverslip from one of the agarose pad slides and added 10 μl of M9 + 6 mM Levamisole to the coverslip, and then re-applied the coverslip to the pad, leaving it on the pad until ~40 sec remained on the count-down timer. When removing the coverslip we also removed as much of the 10 μl as possible along with the coverslip by tilting the coverslip up as soon as it slides off the pad and dragging the liquid away from the pad. We then blotted around the edge of the pad with a Kimwipe to remove excess liquid. When the 6:10 timer finished, we put the coverslip back on the Petri plate lid (wiping the moisture off of the part that contacted the wet Kimwipe square first) and removed 23.5 - 25.5 μl of liquid (average 24.5, but adjusted as needed depending on pad size and wetness after removing the M9) by pipetting under the stereomicroscope. We used a gel loading tip inserted onto a P20 set on the desired volume to remove the liquid in one attempt. The tip of the gel loading tip should be bent sharply, so that the opening points down at the liquid. When applying the new coverslip with worms face down onto the pad, we used a pair of jeweler's forceps to gently lower it onto the pad. On properly mounted coverslips, a small amount of liquid should wick across in all directions and slightly overflow the pad.

Image Acquisition: We acquired images using the same microscope, camera, and computer system described above for static imaging. We adjusted the light power of a SOLA LED light engine to 18% (a good level for reducing bleaching when using the Texas Red filter during the time lapse without compromising signal). We mounted the slide on the microscope and scanned the pad left to right, top to bottom using transmitted light and DIC optics to find the first animal oriented with its ventral cord facing the objective. Using the YFP filter, we then located the DB7 motor neuron and its dendrite and positioned the stage to allow viewing of the soma and as much of the dendrite as possible. At 5:30 min after applying the coverslip, we started the time lapse and continued collecting for 10 min. Each time lapse consisted of 306 frames collected at 2 sec intervals.

Processing Time Lapse Images and Converting them to Kymographs: We used the Review Multidimensional Data Metamorph plug-in to convert the time lapse images into a multi-image TIFF file. We then used the Multi-line tool to trace along the center of the DB7 neuron dendrite, starting at the cell soma boundary and proceeding anterogradely. During tracing we moved back and forth between tracing and the slider such that we could visualize the precise path as CTNS-1-RFP lysosomal puncta moved through the dendrite (i.e. following the puncta by clicking as they move along the dendrite). After ending the trace, we used the Kymograph plug-in to set the line width at a value that included all of the puncta throughout the movie. If animal movement shifted the dendrite's position during the movie, we adjusted the line width to the minimum width that allowed all puncta along the commissure to be included in the boundaries (up to ~50 pixels maximum). If necessary, we additionally shifted the position of the line slightly to compensate for movement. In some cases where animal movement prevented us from make a kymograph that included all frames in the movie, we made kymographs that only included the segments during which puncta moved and used those for analysis, noting that no puncta movements occurred in the frames not included if that was the case. Frames were excluded from the total frame count (used in some of the time calculations) if puncta movements occurred that could not be quantified via kymographs. We then created, reviewed, and saved the Kymograph, used the Save Regions plug-in to save the line traces associated with the file, and noted the optimal line width for each trace.

Quantifying Movements from Kymographs: After opening the multi-plane tiff file, using the Load Regions plug-in to re-load the line traces, and setting the line width at the above determined optimum, we re-created the kymograph (previously saved kymographs can't be used to log data). We then used the Line tool to trace each anterograde movement and logged the Distance and Time data for each movement before repeating for the retrograde movements. A "movement" was defined as being >= 1.25 microns. There is no velocity minimum if the movement is >= 2.0 microns. However, if a movement is < 2.0 microns, it must have a velocity of >= 0.1 microns/ sec. A movement continues until it pauses for >= 30 sec or until it reverses direction, or until it reaches the end of the time course, or until it merges with another punctum and the other punctum does not move (if it merges with another punctum and the combined puncta continue moving, then the movement is considered to continue). Movements that changed their velocity without pausing or changing direction were treated as single point-to-point straight line movements, with one end of the line at the beginning of the movement and the other end at the end of the movement (thus creating an average distance and time from point A to point B). Lysosomal puncta were often elongated, in which case we made point-to-point measurements from the center of the tubule. Sometimes elongated puncta will either stretch, contract, or break apart without actually moving from point to point. These events were obvious from watching the movie and were not treated as point-to-point movements. To quantify puncta entering or exiting the cell soma, we clicked through each time lapse movie to score exit and entry events. If a punctum near the boundary of the soma was elongated, we did not score it as an exit or entry event unless or until the entire length of the punctum had left or entered the cell soma.

Quantifying Percent of Time in Paused State: Pauses were analyzed on all movies having at least 280 frames for movement analysis (out of a maximum of 306 frames). These 280-306 – frame sets were observed for movements/ pauses both frame-by-frame and using kymographs. Because of the occasional movement of puncta out of the field of view, each punctum's time spent paused was compared only to its own total time visible and quantified as a proportion of time visible spent paused (i.e. 0.00 indicating that the punctum never paused and 1.00 indicating that the punctum was paused for the entire time it was visible).

Time lapse movies: We annotated multi-plane TIFF files using Metamorph Display > Graphics > Text or Arrow. We converted selected multi-plane TIFF files to movies using Metamorph Stack > Make Movie > AVI, specifying 3/30ths for each frame (which is 20X faster than real time). Movies were saved as full frames, uncompressed and converted to Quicktime using Wondershare Video Converter Platinum.

C. elegans non- wild type Strains

Strain name	Genotype (origin and/ or first use cited if not produced in this study)

Mutation Lesions and Methods Used for Genotyping in Strain Constructions

Mutation	Description of Molecular Lesion	Effect on Protein	Method(s) used for genotyping	References for mutant isolation and/ or mutation description
cdk-5(gm336)	760 bp deletion that starts in proximal promoter and deletes exons 1, 2, and most of exon 3 (>60% of coding region)	Putative null	PCR with primers inside deleted region	(Juo *et al.* 2007)
cdk-5(tm613)	428 bp deletion extending from middle of exon 3, including all of exon 4, and ending in intron 4.	Putative null	PCR with primers inside deleted region	Japanese National Bioresource Project for the Experimental Animal "Nematode *C. elegans*" and this study.
nab-1(ok943)	1032 bp deletion that deletes coding region exons common to all isoforms, including all of the region encoding the coiled-coil domain.	Putative null	PCR with primers inside deleted region	*C. elegans* Gene Knockout Consortium and (Hung *et al.* 2007)
nud-2(ok949)	1109 bp deletion and a 1 bp insertion. Starts at the predicted ATG of nud-2 and deletes the entire open reading frame except the last part of the last exon.	Putative null	PCR with primers inside deleted region	*C. elegans* Gene Knockout Consortium and (Fridolfsson *et al.* 2010)
pct-1(tm2175)	733 bp deletion with a 5 bp insertion (GAGAG). Removes the kinase domain in all 3 isoforms.	Putative null	PCR with primers inside deleted region	Japanese National Bioresource Project for the Experimental Animal "Nematode *C. elegans*" and (Ou *et al.* 2010)
sad-1(ce749)	Q57Stop (out of 835 or 914 amino acids, depending on the isoform). Mutation position is the same in both isoforms.	Putative null	Make 250 bp PCR product centered on the mutation, followed by restriction digest with Mse I (the mutation creates an Mse I site).	This study
sad-1(ce753)	R147Stop nonsense mutation	Putative null	Make 500 bp PCR product centered on the mutation, followed by restriction digest with Bst UI (site is only present in wild type).	This study
strd-1(ok2283)	1015 bp deletion that deletes from amino acid R174 onward	Putative null	PCR with primers inside deleted region	*C. elegans* Gene Knockout Consortium and

					(Kim *et al.* 2010)
syd-1(tm6234)	1266 bp deletion starting in the intron between exons 7 and 8 and ends in the middle of exon 11 of the "b" isoform. The deletion eliminates R249 – Y471 (out of 942 amino acids total) and results in a frame shift predicted to prevent translation of the remaining protein.	Putative null	Behavioral phenotypes and PCR with primers inside deleted region	Japanese National Bioresource Project for the Experimental Animal "Nematode *C. elegans*" and this study.	
syd-2(ce759)	Q387Stop (out of 1139 amino acids total)	Putative null	Behavioral phenotypes and PCR followed by sequencing	This study	
syd-2(ok217)	~2 Kb deletion covering most of the N-terminal coiled coil domains. Results in a frame shift and stop codon at amino acid 200 (out of 1139 amino acids total).	Putative null	Behavioral phenotypes and PCR with primers inside deleted region	*C. elegans* Gene Knockout Consortium and (Wagner *et al.* 2009; Kittelmann *et al.* 2013)	
unc-16(ce483)	Q304Stop (out of1157 amino acids of the ZK1098.10b isoform)	Putative null	Behavioral phenotypes and PCR followed by sequencing	(Edwards *et al.* 2013)	
unc-104(ce782)	Missense mutation G105E in motor domain	Conditional strong reduction-of-function or null	Behavioral phenotypes and PCR followed by sequencing	(Edwards et al., co-submitted)	
unc-104(e1265)	Missense mutation D1497N in the cargo binding domain	strong reduction-of-function	Behavioral phenotypes and PCR followed by sequencing	(Kumar *et al.* 2010)	

Plasmids

KG#65	unc-17β:: expression vector	(Charlie *et al.* 2006)
KG#67	ttx-3::GFP	Gift of Oliver Hobert, Columbia University
KG#230	unc-129:: expression vector	(Edwards *et al.* 2009)
KG#240	unc-129::___-mCherry expression vector	(Edwards *et al.* 2009)
KG#255	ttx-3::RFP	(Edwards *et al.* 2009)
KG#367	unc-129:___-GFP	(Edwards *et al.* 2013)
KG#374	unc-129::___-Venus expression vector	(Edwards *et al.* 2009)
KG#414	unc-129::RFP-SYN-13	(Edwards *et al.* 2013)
KG#428	unc-129::SYD-2-GFP	Used Pfu Ultra polymerase and primers engineered with restriction sites to amplify the 5.4 Kb syd-2 gene coding region (minus its stop codon and with reading frame adjusted for fusing to GFP) from purified N2 genomic DNA and clone into Nhe I/ Kpn I cut KG#367 (unc-129::___-GFP).
KG#611	unc-129::PST-2A-CFP	(Edwards *et al.* 2013)
KG#695	unc-129::SAD-1A-GFP	Used AffinityScript Multiple Temperature Reverse Transcriptase and a primer engineered with a restriction site to make the sad-1 ("a" isoform) cDNA (2.7 Kb). Then used Herculase II polymerase and primers engineered with restriction sites to amplify and clone the cDNA into Nhe I/ Kpn I cut KG#367 (unc-129::___-GFP expression vector; 7.2 Kb).
KG#696	unc-17β::sad-1a cDNA	Used Herculase II polymerase and primers engineered with restriction sites to amplify the 2.7 Kb sad-1 ("a" isoform) cDNA from KG#695 and cloned it into Nhe I/ Kpn I cut KG#65 (unc-17β ::___ expression vector; 4.2 Kb).
KG#717	unc-129::SAD-1 cDNA	Used Nhe I/ Kpn I to cut out the 2.7 Kb sad-1a cDNA from KG#696 (unc-17 ::sad-1a cDNA) and cloned it into the like-digested unc-129:: vector KG#230 (6400 bp). Transform into XL1-Blue electrocompetent cells.
KG#718	unc-129::CDK-5 cDNA	Used AffinityScript Multiple Temperature Reverse Transcriptase and a primer engineered with a restriction site to make the *cdk-5* cDNA. Used Herculase II polymerase and primers engineered with restriction sites to amplify and clone the cDNA into Nhe I/ Kpn I cut KG#230.
KG#739	unc-17::__-GFP	Used Age I/ Apa I to cut out the ~1000 bp unc-54 3' control region from KG#65, leaving the 3.2 kb vector fragment containing the *unc-17β*:: promoter To this vector fragment, we ligated the 1800 bp Age I/ Apa I fragment (containing GFP + unc-54 3' control region) cut from pPD94.81.
KG#740	unc-17::PST-2A-GFP	Used Nhe I/ Age I to cut out the 1.1 Kb *pst-2a* cDNA from KG#611 (*unc-129*::PST-2A-CFP) and cloned it into like-digested KG#739 (unc-17 ::__-GFP vector).
KG#751	unc-129::PST-2A-GFP	Used Nhe I/ Age I to cut out the 1.1 Kb *pst-2a* cDNA from KG#740 (*unc-17*::PST-2A-GFP) and cloned it into the like-digested unc-129::__-GFP vector KG#367.
KG#804	unc-129::SYD-2 gene	Used the Q5 Site-Directed Mutagenesis Kit (New England Biolabs) to insert a stop codon after the SYD-2 gene in KG#428 (unc-129::SYD-2-GFP).
pPD94.81	unc-54::GFP	Gift of Andrew Fire, Stanford University
pPD118.33	myo-2::GFP	Gift of Andrew Fire, Stanford University

Transgenic Arrays and Genomically Integrated Transgenes

Array name	Insertion location	Experimental contents and injection concentrations	Co-transformation markers and injection concentrations	References for transgene or integrated insertion (if not made in this study)

ceEx450	extrachromo somal array	KG#718 [unc-129::CDK-5 cDNA] (30 ng/ μl)	KG#67 [ttx-3::GFP] (25 ng/ μl)	This study
ceEx472	extrachromo somal array	KG#717 [unc-129::SAD-1a cDNA] (2 ng/ μl)	pPD118.33 [myo-2::GFP] (0.75 ng/ μl)	This study
ceEx474	extrachromo somal array	KG#804 [unc-129::SYD-2 gene] (1.5 ng/ μl)	pPD118.33 [myo-2::GFP] (0.75 ng/ μl)	This study
ceIs56	X: ~9.0	KG#371 [unc-129::CTNS-1a-RFP] (5 ng/ μl)	KG#255 [ttx-3::RFP] (15 ng/ μl) KP#1383 unc-129::NLP-21-Venus (15 ng/ μl)	(Edwards *et al.* 2009; Edwards *et al.* 2013)
ceIs134	V: ~ -2.0	KG#645 [unc-17β::CTNS-1A-RFP] (3.5 ng/ μl)	RM#605p [unc-17β::GFP] (10 ng/ μl)	(Edwards *et al.* 2013)
ceIs259	IV: ~3.4	KG#414 [unc-129::RFP-SYN-13] (1.0 ng/ μl) KG#374 [unc-129::mCherry] (1.0 ng/ μl)	KG#255 (ttx-3::RFP) (15 ng/ μl)	This study
ceIs267	V: -1.9 or 11.2	KG#751 [unc-129::PST-2-GFP] (0.35 ng/ μl) KG#240 [unc-129::mCherry] (1.0 ng/ μl)	KG#255 (ttx-3::RFP) (15 ng/ μl)	This study

File S2. Time lapse of lysosome movements between DB7 and its dendrite in wild type.

File S2 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma, dendrite, and axonal commissure of the cholinergic motor neuron DB7 from a wild type adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S3. Time lapse of lysosome movements between DB7 and its dendrite in *cdk-5(gm336).*

File S3 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma, dendrite, and axonal commissure of the cholinergic motor neuron DB7 from a *cdk-5(gm336)* adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S4. Time lapse of lysosome movements between DB7 and its dendrite in *sad-1(ce749).*

File S4 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma and dendrite of the cholinergic motor neuron DB7 from a *sad-1(ce749)* adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S5. Time lapse of lysosome movements between DB7 and its dendrite in *syd-2(ok217).*

File S5 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma and dendrite of the cholinergic motor neuron DB7 from a *syd-2(ok217)* adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S6. Time lapse of lysosome movements between DB7 and its dendrite in *unc-16(ce483).*

File S6 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma, dendrite, and axonal commissure of the cholinergic motor neuron DB7 from an *unc-16(ce483)* adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S7. Time lapse of lysosome movements between DB7 and its dendrite in *unc-16(ce483) cdk-5(gm336).*

File S7 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma, dendrite, and axonal commissure of the cholinergic motor neuron DB7 from an *unc-16(ce483) cdk-5(gm336)* adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S8. Time lapse of lysosome movements between DB7 and its dendrite in *unc-16(ce483); sad-1(ce749).*

File S8 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma and dendrite of the cholinergic motor neuron DB7 from an *unc-16(ce483); sad-1(ce749)* adult. The actual length of the time lapse is 10 min (acquired at 1 frame/ 2 sec), but the movie has been sped up ~20 – fold (to 30 sec).

File S9. Time lapse of lysosome movements between DB7 and its dendrite in *unc-16(ce483); syd-2(ok217).*

File S9 is available for download at www.genetics.org/lookup/suppl/doi:10.1534/genetics.115.177345/-/DC1. Shown are the cell soma and dendrite of the cholinergic motor neuron DB7 from an *unc-16(ce483); syd-2(ok217)* adult.
