ABSTRACT Leucine-rich repeat (LRR) is a versatile motif widely present in adhesive proteins and signal-transducing receptors. The concave structure formed by a group of LRRs is thought to facilitate binding to globular protein domains with increased affinities. However, little is known about the conformational dynamics of LRRs in such a structure, e.g., whether and how force induces conformational changes in LRRs to regulate protein binding and signal transduction. Here we investigated the platelet glycoprotein Ib α (GPIb α), a demonstrated mechanoreceptor with known crystal structures for the N-terminal domain (GPIb α N), as a model for LRR-containing proteins using a combined method of steered molecular dynamics simulations and single-molecule force spectroscopy with a biomembrane force probe. We found that force-induced unfolding of GPIb α N starts with LRR2–4 and propagates to other LRRs. Importantly, force-dependent lifetimes of individual VWF-A1 bonds with GPIb α are prolonged after LRR unfolding. Enhancement of protein-protein interactions by force-induced LRR unfolding may be a phenomenon of interest in biology.

Binding of von Willebrand factor (VWF) to platelet membrane receptor glycoprotein Ib α (GPIb α) initiates hemostasis and thrombosis under high shear conditions, mostly seen in arteries and restricted vessels [\(1](#page-3-0)). VWF is a multimeric protein composed of identical 250-kDa subunits. Each subunit has a single 24-kDa A1 domain that binds to the 45 kDa, \sim 280 residues, N-terminal domain of GPIb α (GPIb α N). The crystal structures of the A1-GPIb α N complex $(2,3)$ $(2,3)$ $(2,3)$ reveal that GPIb α N consists of eight leucine-rich repeats (LRRs, K19–L208) that form an elongated shape (cf. [Fig. 1](#page-1-0) A). The concave LRR framework grabs the A1 in a pincerlike grip with an N-terminal contact (involving the β -finger motif and LRR1) and a C-terminal contact (involving LRR5–8 and the β -switch loop). Intriguingly, the middle portion of the GPIb α N, from LRR2–4, makes no contacts to the A1 in the crystal structures; yet, these LRRs are required for ristocetin-dependent and shear dependent VWF binding ([4\)](#page-3-0). Because crystal structures were obtained in the absence of force, they provide little insight into any possible conformational change induced by shear.

Single-molecule force spectroscopic studies using atomic force microscopy, an optical trap, and a biomembrane force probe (BFP) suggested that at least two conformational states may exist upon formation of the receptor-ligand complex [\(5](#page-3-0)). A recent crystal structure of a gain-of-function mutant A1 complexed with GPI $b\alpha$ N revealed A1 interaction

with LRR3-5 that further enhances the A1-GPIb α N affinity ([6\)](#page-3-0). These findings suggest that force may induce a conformational change that alters the central $A1$ -GPIb α LRR contact to enhance affinity.

Force induces LRR conformational change on A1-GPIb α bond in simulations

To investigate whether the force applied on the $A1-GPIb\alpha$ complex can cause significant protein conformational change, we carried out 11 independent steered molecular dynamics (SMD) simulations and observed in four trajectories unfolding of GPIbaN before dissociation from A1. At the starting point $(t = 0)$, GPIbaN contacts A1 via the β -switch and β -finger [\(Fig. 1](#page-1-0) A). At $t > 0$, the C α atom of GPIb α N C-terminal residue L267 was pulled to move horizontally at a constant speed to the right with the Ca atom of the A1 N-terminal residue H1268 harmonically constrained. Upon loosening of the β -switch from the A1 central β -sheet at 9 ns ([Fig. 1](#page-1-0) B), the GPIb α N started to tilt about the β -finger–A1 hinge point, a counterclockwise rotation that continued throughout the remainder of the simulations. At 10 ns, the GPIb α β -switch

FIGURE 1 SMD simulation of GPIb α N dissociation from the A1 domain. Sequential snapshots of representative SMD-simulated structures revealing that force induces GPIb α N unfolding in the middle region of GPIb α N (LRR2-4). (Blue, A1; red, $GPlb_{\alpha}N$.) The equilibrated structure (A) was used as the starting structure for SMD simulations, which generated the structures in (B) – (F) at the indicated times. To see this figure in color, go online.

dissociated from the A1 central β -sheet, but the β -finger remained bound to A1, although interacting with different A1 residues from those seen at 0 ns $(Fig. 1 C)$. At 11 ns, several hydrophobic interactions near the $GPIb\alpha N$ β -finger were ruptured by further pulling (Fig. 1 D). Surprisingly, a few residues spanning the LRR3, T68–L89, uncoupled from each other and became loose. At 12 ns, the LRR3 was completely unfolded and extended by force (Fig. 1 E). At 14 ns, the region below LRR3, e.g., LRR4, started getting loose; however, the GPIbaN dissociated from A1 before complete unfolding of LRR4 was observed (Fig. 1 F). Additional simulations with different force loading rates and anchor points showed similar LRR unfolding behavior (Fig. S1 in the [Supporting](#page-2-0) [Material](#page-2-0)). Regardless of the anchor point, GPIbaN unfolding started at LRR2-3 in a fast pulling process, suggesting that rapid loading facilitates LRR extension (Fig. S1, B and C).

Experimental characterization of force-induced conformational change in individual A1-GPIb α complexes

We next used the previously described BFP force spectroscopy $(7,13)$ to observe conformational change in single A1-GPIba complexes and its impact on force-dependent bond lifetimes [\(Fig. 2](#page-2-0), A and B). In the BFP force traces, a sudden force drop occurring at 5–20 pN, caused by an abrupt length increase between the probe and the target, was consistently (~14% occurrence) observed in the retraction phase when a ramp force (1000 pN/s) was applied to the extracellular portion of GPIba, glycocalicin (GC), via A1 ([Fig. 2](#page-2-0), C and E). Pulling GC via a monoclonal antibody (mAb) HIP1 yielded a similar unfolding occurrence as pulling via A1 (Fig. $2 E$). In contrast, unfolding event was eliminated when HIP1 was replaced by another mAb SZ2 on the probe or when GC was replaced by an anti-A1 mAb 5D2 on the target [\(Fig. 2,](#page-2-0) D and E). This indicates that it was GC, not A1, that was being unfolded, and that unfolding occurred within the LRR region, because the binding epitope of SZ2 is mapped to the anionic region below all LRR domains (8) (8) [\(Fig. 2](#page-2-0) G).

The force-extension analysis showed that the extension lengths range from the minimum of 18 nm ($l_{\text{min}} =$ length of one LRR, assuming a contour length of 4 Å per residue) to the maximum of 56 nm (l_{max} = length of six LRRs) ([Fig. 2](#page-2-0), F and G). Surprisingly, the A1–GC unfolding length histogram right-shifted when force loading rate was increased from 1000 to 3000 pN/s (Fig. 2 F). The unfolding length difference between the $l_{\text{max}}(3000 \text{ pN/s})$ (= 69 nm, i.e., LRR2-8) and $l_{\text{max}}(1000 \text{ pN/s})$ (= 56 nm, i.e., LRR3–8) is \sim 13 nm [\(Fig. 2](#page-2-0) G), matching the length difference (-11 nm) between the unfolding starting points (LRR2 to LRR3) by different SMD ramping processes (Fig. S1). The combined SMD simulations (Figs. 1 and S₁) and the BFP results indicated that force can unfold multiple repeats of the LRR region starting from the noncontact LRR2-4.

To investigate the functional consequence of the forceinduced GPIba unfolding, we measured lifetimes of A1 bonds with GC on a bead ([Fig. 3](#page-3-0) A) or GPIb α on a platelet ([Fig. 3](#page-3-0) B). Consistent with our previous reports $(7,9,13)$ $(7,9,13)$, force counterintuitively prolongs bond lifetime (catch bond) from 10 to 25 pN. Further increase in force reduces bond lifetime (slip bond). To delineate the role of forceinduced unfolding, we segregated the lifetimes into two subgroups based on whether an unfolding event was observed in the force-ramp phase ([Fig. 2](#page-2-0) C). In $>$ 20 pN forces, however, bond lifetimes with unfolding events became longer than those without unfolding events (Fig. 3 , A and B). This indicates that GPIb α unfolding can immediately prolong the lifetime of its bond with VWF-A1.

Most studies on the effect of force on the structure of the VWF-GPIb α axis focus on shear-induced conformational changes in the VWF. As a long molecule (>40 nm above the membrane) [\(10](#page-3-0)), however, GPIb α may also appear susceptible to the conformational change upon force application. A recent study identified a mechanosensitive domain in the juxtamembrane region below the GC portion that can be unfolded by pulling force (11) (11) . The authors suggest that no other $GPIb\alpha$ region can be unfolded, as mutations in this mechanosensitive domain abolished the force-induced unfolding they observed.

FIGURE 2 GPIb α N unfolding observed by BFP force-clamp assay. (A) BFP photomicrograph. A micropipette-aspirated RBC with a bead (left, probe) attached to the apex formed a picoforce sensor. It was aligned with another bead (right, target) aspirated by an apposing micropipette. (B) BFP functionalization with indicated molecules. $(C \text{ and } D)$ Force versus time traces from representative force-clamp cycles for A1-GC bond lifetime measurement (C) and antibody-protein stretch assay (D). (Inset) The putative unfolding event is circled and zoomed-in to show the details. (E) Occurrence frequencies of unfoldingversus-no-unfolding events (numbers are indicated in yellow) from all binding events mediated by the indicated interactions. (F) Normalized histograms (bar) and their Gaussian fits of unfolding length. (G) Glycocalicin schematic (left) and GPIb α N domain organization (right). Starting and ending residues for each domain as well as the binding epitopes of two anti-GPIb α mAbs are all indicated. To see this figure in color, go online.

Here we show GPIbaN conformational changes that enhance binding to VWF-A1, indicating the functional relevance of the LRR unfolding. Our results suggest that force extends the GPIbaN concave structure by unfolding a few LRRs, allowing the globular A1 domain to fit better into the enlarged binding pocket and reach a longer-lived state [\(Fig. 3](#page-3-0) C). This may explain platelets agglutination via VWF-GPIb α bonds without activation or binding of integrin GPIIb/IIIa at sites of atherothrombosis where severe vessel narrowing produces extremely high shears $(>10,000 \text{ s}^{-1})$ [\(12](#page-3-0)). Whether GPIb α mechanosensitivity endows this molecule with the capacity of mechanosensing requires future studies.
