Abstract: Objective: Cystatin C is a well established marker of kidney function. There is evidence that cystatin C concentrations are also associated with myocardial infarction. The purpose of the present study is to clarify the link between cystatin C with myocardial infarction using a meta-analysis approach. Methods: We searched articles indexed in the Pubmed and Sciencedirect published as of August 2015 that met our predefined criteria. A meta-analysis was used to pool estimates of the multivariate adjusted relative risk (RR) with 95% confidence interval (CI), of the association between cystatin C and subsequent risk of myocardial infarction. Results: Four eligible articles with 10491 subjects from 5 cohort studies were considered in the analysis. Overall, the random-effects meta-analysis results indicated that the highest cystatin C category versus lowest was associated with greater risk of myocardial infarction (RR, 1.78; 95% CI, 1.27 to 2.49; $P=0.001$). No evidence of publication bias was observed. Conclusions: This meta-analysis showed that cystatin C is strongly and independently associated with subsequent risk of myocardial infarction. Further investigation is warranted to clarify whether measurement of cystatin C can usefully reduce the myocardial infarction beyond established predictors already in clinical use.

Keywords: Cystatin C, risk factor, myocardial infarction, meta-analysis

Introduction

Chronic kidney disease, a worldwide health problem, is associated with a substantial risk for cardiovascular morbidity [1-3]. In clinical practice and in epidemiological research studies, glomerular filtration rate (GFR) is considered to be the best overall index of kidney function. However, the widely used creatinine-based modification of renal disease study formula for GFR still has substantial inaccuracy when applied to healthy persons and older individuals mass [4]. Recently, the use of serum creatinine-based formulas to assess renal function has been challenged by novel markers, particularly cystatin C, which may be a more reliable index of renal function [5, 6].

Cystatin C, as an improved estimate of GFR, is a cysteine protease inhibitor produced by nearly all human cells and excreted into the bloodstream and do not depend on muscle mass. At

a molecular weight of 13 kD, the protein is eliminated exclusively by glomerular filtration and tubular reabsorption with subsequent catabolism [7, 8]. It has been reported that GFR equations that incorporate the cystatin C concentration may perform better in the normal GFR range than those relying on creatinine [9, 10]. As a marker of renal function, cystatin C is a powerful tool for risk evaluation of cardiovascular disease above and beyond its role as a surrogate for GFR [11, 12]. Observational studies suggest that cystatin C is strongly and independently associated with subsequent risk of myocardial infarction [13-16]. Shlipak et al. reported a statistically significant association between the incidence of myocardial infarction and the elevated cystatin C in 4637 patients [14]. Windhausen et al. demonstrated a similar result in 1128 patients [15]. Negrusz-Kawecka et al. suggested that the high cystatin C level plays a role in the pathogenesis of myocardial

Cystatin C and myocardial infarction

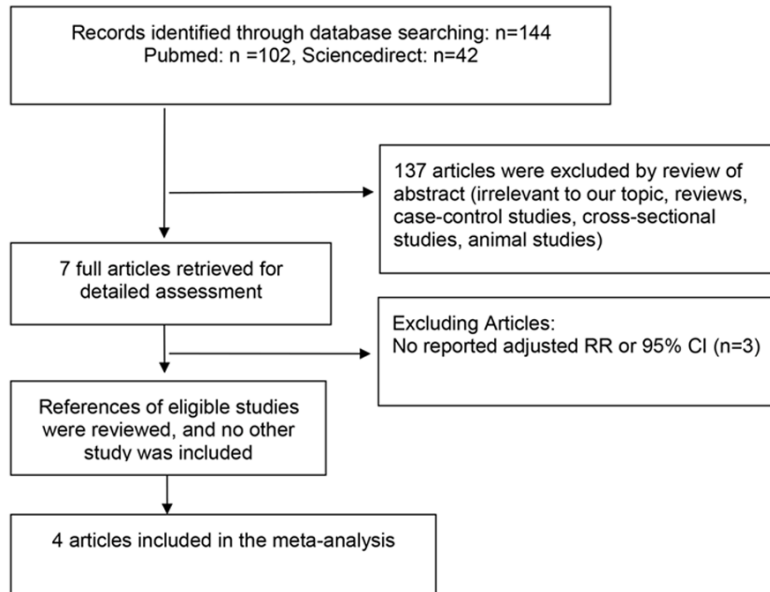

Figure 1. Flow diagram of screened and included papers.

infarction in 63 patients [16]. However, no systematic review has been conducted to evaluate the totality of available evidence regarding a link between cystatin C and subsequent risk of myocardial infarction.

Meta-analysis is a well-established statistical tool that serves for integration of data from independent studies in order to formulate more general conclusions. We therefore undertook a meta-analysis of cohort studies to qualitatively and quantitatively assess the association between cystatin C and risk of myocardial infarction.

Materials and methods

Search strategy

We searched all English written articles indexed in Pubmed and Science direct published up to August 2015. literature searches were performed using medical subject heading (MeSH) or free text words. The searching keywords were: cystatin C AND myocardial infarction. Reference lists of all eligible studies were screened to identify potentially eligible studies. Emails were sent to the authors of identified studies for additional information if necessary.

Selection criteria

The search was conducted by three authors independently. Titles and abstracts were

screened for subject relevance. Studies that could not be definitely excluded based on abstract information were also selected for full text screening. Two authors independently selected eligible studies for inclusion possibility. Where there was a disagreement for study inclusion, a discussion was held to reach a consensus. Eligible studies had to meet the following criteria: (1) human study; (2) cohort study or clinical trial; (3) cystatin C measured at baseline; (4) reported myocardial infarction as outcomes; (5) reported quantitative estimates of the multivariate adjusted relative risk (RR)

and 95% confidence interval (CI) for the outcomes associated with baseline cystatin C. Exclusion criteria included: (1) animal study, review or case report; (2) in vitro or laboratory study; (3) the majority of participants had end-stage renal disease (dialysis or GFR <15 mL/min/1.73 m²) or kidney transplant; (4) the study only reported unadjusted RR, or not reported 95% CI, or data were duplicative; (5) sample less than 20.

Data extraction and quality assessment

The following information was extracted from each included study: country, first author's family name, year of publication, demography of subjects (number of subjects, sex and age), year of follow-up, cystatin C levels, adjusted RR and 95% confidence interval. Two authors independently extracted data using a standard form. Discrepancies were resolved by discussion with a third investigator and by referencing the original report. Our primary outcomes of interest were the association of myocardial infarction and cystatin C categorical level, based on the comparison of the highest category of cystatin C versus lowest.

Two authors assessed the quality independently. The qualities of all included studies were assessed using the Newcastle-Ottawa Scale (NOS). Quality assessment was conducted in

Cystatin C and myocardial infarction

Table 1. Characteristics of subjects in eligible studies

Studies	Country	Population	Participant No. (Women, %)	Mean Age, y	Follow-Up, year	Comparison Cystatin C Level, mg/L	Adjusted risk factors	Study quality
Shlipak 2005	USA	Elderly ages ≥ 65 y	4637 (58)	75	7.4	Highest quintile (>1.29) vs lowest (<0.89)	age, sex, diabetes, left ventricular hypertrophy, fibrinogen level, C-reactive protein, hemoglobin level, myocardial infarction, stroke, and heart failure	6
Shlipak 2006-1	USA	Elderly ages ≥ 65 y	3659 (NA)	>65	9.3	Highest quintile (≥ 1 mg/L) vs lowest (<1 mg/L)	age, sex, race, low-density lipoprotein cholesterol level, high-density lipoprotein cholesterol level, hypertension, diabetes, current smoking, C-reactive protein level, prevalent heart failure, coronary artery disease, stroke, height, weight, and physical activity. Cystatin C and creatinine concentrations	5
Shlipak 2006-2	USA	Elderly ages ≥ 65 y	1004 (NA)	>65	9.3	Highest quintile (≥ 1 mg/L) vs lowest (<1 mg/L)	age, sex, race, low-density lipoprotein cholesterol level, high-density lipoprotein cholesterol level, hypertension, diabetes, current smoking, C-reactive protein level, prevalent heart failure, coronary artery disease, stroke, height, weight, and physical activity. Cystatin C and creatinine concentrations	5
Windhausen 2009	Netherlands	Acute coronary heart disease	1128 (27)	62	3	Highest quintile (>1.01) vs lowest (<0.86)	age, sex, diabetes, coronary heart disease, hypertension, myocardial infarction, hypercholesterolemia, tobacco use, drug therapy	7
Negrusz-Kawecka 2014	Poland	coronary artery disease	63 (39)	62.7	0.5	Highest quintile (≥ 0.915 mg/L) vs lowest (<0.915 mg/L)	gender, age, diabetes mellitus, arterial hypertension, CKD, nicotine abuse and obesity	7

Cystatin C and myocardial infarction

Figure 2. Forest plot of studies in the association between cystatin C with myocardial infarction.

three domains: subject selection, comparability of groups and the ascertainment of outcomes. The total NOS Star count ranges from zero to nine. A rating of 5 or more was considered to be indicative of a higher quality study.

Statistical analysis

Data analyses used the Multivariate-adjusted outcome data expressed as RRs and 95% CIs. We pooled risk estimates comparing the highest to the lowest category of cystatin C. Heterogeneity between studies was tested through the Chi-square and I-square tests. If the I^2 value was greater than 50% and the p value was less than 0.10, the meta-analysis was considered as homogeneous. The RRs were calculated using either fixed-effects models or, in the presence of heterogeneity, random-effects models.

Subgroup analyses were used to identify the possible sources of heterogeneity. Subgroup analyses were conducted based on the following characteristics: location, mean age, follow-up duration, cutoff point of the lowest interval of cystatin C, and cutoff point of the highest interval of cystatin C. The stability of the study was also detected by sensitivity analysis, through re-meta-analysis with one involved study excluded each time. Publication bias was measured using Begg's tests and visualization of funnel plots. All statistical analyses were performed with Stata version 11.0 (Stata Corp, College Station, TX, USA). A p value less than 0.05 was considered statistically significant.

Results

Literature search

The systematic literature review identified 7 full articles for detailed assessment, among which 3 were excluded for not reporting RR and 95% CI for the risk of myocardial infarction. Overall, 4 eligible articles with 10491 subjects from 5 cohort studies were considered in the analysis [13-16]. A flow diagram of the study selection process is presented in **Figure 1**.

Study characteristics and quality assessment

The detailed characteristics of the included studies and the results of the quality assessment were summarized in **Table 1**. By geographic location, studies were conducted in 3 different countries (USA, Poland, Netherlands). The earliest study was published in 2005, and the latest in 2014. The mean age of population ranged from 62 to 75 years. All study included both men and women. The number of subjects in each study ranged from 63 to 4637. The follow-up duration ranged from 0.5 to 9.3 years. The RR is adjusted for other risk factors, such as age, sex, diabetes, myocardial infarction, heart failure, blood pressure, high-density lipoprotein cholesterol level, total cholesterol or low-density lipoprotein cholesterol level, smoking, body-mass index and C-reactive protein. The overall study quality was good (averaged 6; range 5-7) on a scale of 0 to 9 point.

Cystatin C level and myocardial infarction

The random-effects meta-analysis results indicated that the highest cystatin C category versus lowest was associated with greater risk of myocardial infarction (RR, 1.78; 95% CI, 1.27 to 2.49; $P=0.001$) (**Figure 2**). The 5 sets of results showed significant amount of heterogeneity ($I^2=72.4%$, $P=0.006$) (**Figure 2**).

Potential sources of heterogeneity in the strength of the association between cystatin C (highest category versus lowest) and subsequent risk of myocardial infarction were examined by conducting subgroup analyses (**Table**

Cystatin C and myocardial infarction

Table 2. Differences between studies by subgroup analysis

Subgroups	Number of studies	RR (95% CI)	Heterogeneity within subgroups	Heterogeneity among subgroups
Location				
USA	3	1.594 (1.125, 2.259)	$I^2=79.8\%$, $P=0.075$	$I^2=27.2\%$, $P=0.241$
Europe	2	3.101 (1.078, 8.924)	$I^2=54.9\%$, $P=0.340$	
Duration of follow-up				
≤ 5 years	3	1.594 (1.125, 2.259)	$I^2=79.8\%$, $P=0.075$	$I^2=27.2\%$, $P=0.241$
> 5 years	2	3.101 (1.078, 8.924)	$I^2=54.9\%$, $P=0.340$	
Cutoff point of the highest interval of cystatin C				
>1 mg/L	2	2.238 (1.740, 2.880)	$I^2=0\%$, $p=0.741$	$I^2=66.6\%$, $P=0.084$
≤1 mg/L	3	1.499 (1.027, 2.187)	$I^2=62.6\%$, $P=0.061$	
Mean age				
≥ 65 years	3	1.594 (1.125, 2.259)	$I^2=79.8\%$, $P=0.075$	$I^2=27.2\%$, $P=0.241$
< 65 years	2	3.101 (1.078, 8.924)	$I^2=54.9\%$, $P=0.340$	
Cutoff point of the lowest interval of cystatin C				
<0.90 mg/L	2	2.238 (1.740, 2.880)	$I^2=0\%$, $p=0.741$	$I^2=66.6\%$, $P=0.084$
≥0.90 mg/L	3	1.499 (1.027, 2.187)	$I^2=62.6\%$, $P=0.061$	

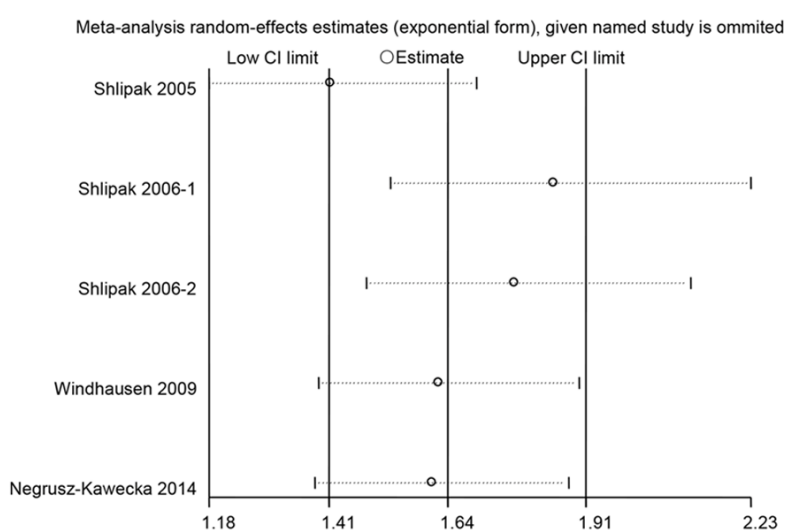

Figure 3. The stability of the study was detected through sensitivity analysis.

2). Significant heterogeneity between pooled analyses were noted for study location (USA versus Europe, $I^2=66.6\%$, $P=0.084$), mean age (<65 years versus ≥65 years, $I^2=66.6\%$, $P=0.084$), follow-up duration (≤5 years versus >5 years, $I^2=66.6\%$, $P=0.084$). There was no evidence that the strength of the association differed according to cutoff point of the lowest interval of cystatin C (<0.90 mg/L versus ≥0.90 mg/L, $I^2=27.2\%$, $P=0.241$), and cutoff point of the highest interval of cystatin C (>1 mg/L versus ≤1 mg/L, $I^2=27.2\%$, $p=0.241$).

Sensitivity analysis and publication bias

Sensitivity analysis showed that excluding any one study from the pooled analysis did not vary the results substantially (**Figure 3**). Publication bias was determined by Begg's test and visualization of funnel plot. There was no evidence of publication bias ($P=0.436$) (**Figure 4**).

Discussion

Chronic kidney disease is a growing problem in everyday clinical practice, and is proven as a significant risk factor for cardiovascular disorders. It has been reported for many years that patients with end-stage renal disease have a high prevalence of cardiovascular disease [17]. Previous studies also find that mild to moderate renal impairment has also been shown to be strongly associated with cardiovascular events in patients in the general population [18, 19]. Cystatin C has been shown to be a better endogenous marker of GFR than creatinine in chronic kidney disease [20]. With the introduction of rapid, sensitive, and precise

Cystatin C and myocardial infarction

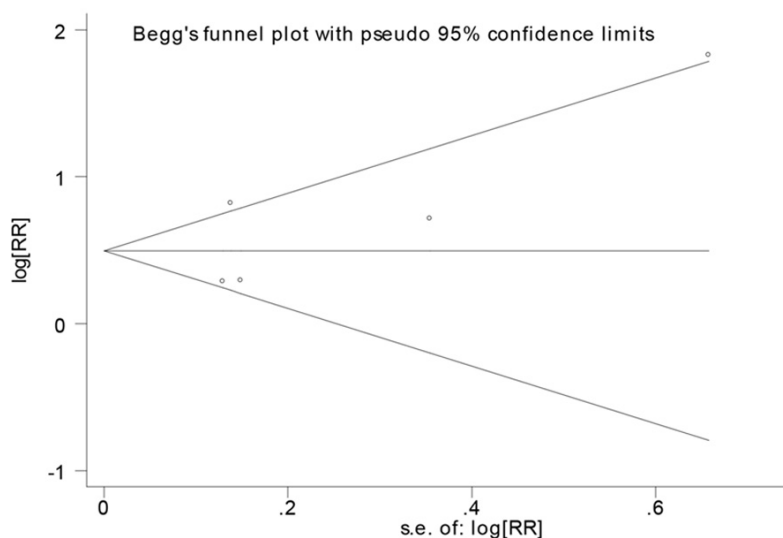

Figure 4. Funnel plot for studies in the association between cystatin C with myocardial infarction.

immunoassays, it is now possible to use cystatin C as a marker of renal function routinely in the clinic. Recently, a clinic study of 9988 participants, which investigated cystatin C to predict coronary heart disease and heart failure, found that higher cystatin C concentrations were associated strongly with cardiovascular disorders and more predictive than GFR [21]. Thus, as a marker of renal function, cystatin C is a powerful tool for risk evaluation of cardiovascular disease above and beyond its role as a surrogate for GFR. The strong association between renal function and cardiovascular disorders probably is explained by several cooperating mechanisms. One reason is that renal dysfunction indicates a generalized atherosclerosis and vascular damage [22]. In addition, being a marker of increased risk, renal dysfunction may directly promote atherosclerosis by causing changes in parameters such as blood pressure, lipids, lipoproteins, homocysteine, and CRP [23]. Cystatin C which is produced and secreted by cardio myocytes, its synthesis is elevated when the heart is subjected to ischemia, and its accumulation can lead to adverse effects, such as a build-up of amyloid deposits in vascular walls [16, 24].

In the present study, Our meta-analysis of over 10000 participants from 4 articles with 5 prospective studies showed that, compared with individuals with the lowest baseline cystatin C levels, those with the highest levels have a 78%

increase in the risk of myocardial infarction. All studies included in our meta-analysis reported a multivariate-adjusted relative risk, mitigating the possibility of known confounding influencing our results. Cystatin C is not only a filtration marker, but also more important a tool for predicting the risk of myocardial infarction. This may be a result of extra renal effects of molecules previously considered exclusively indicating GFR [25]. For instance, cystatin C is affected by smoking, obesity, and inflammation, which themselves may be

associated with increased risk [26-28]. Therefore, we performed the meta-analysis using multivariate-adjusted relative risk (RR) and 95% confidence interval (CI), and adjusted our analyses for these and conventional risk factors of myocardial infarction. Importantly, we found significantly increased probability of myocardial infarction across all the included studies, suggesting the possibility that cystatin C has an active role in biological processes leading to myocardial infarction.

As far as we know, this is the most comprehensive meta-analysis to estimate the association between cystatin C with myocardial infarction. We made sure to minimize the bias by means of study procedure. Not only did we search Pubmed and Science direct to identify potential studies, but also we manually examined all reference lists from relevant studies. The inclusion of only longitudinal studies strengthened the robustness of our findings because issues of selection bias, recall bias, and reverse causality were minimized. Sensitivity analysis showed that excluding any one study from the pooled analysis did not vary the results substantially. Publication bias was also absent, as determined by visualization of funnel plot and Begg's test. However, the possible limitations of our study must be considered. First, the studies varied with respect to the characteristics of participants and follow-up duration, and indeed heterogeneity of the studies was found

Cystatin C and myocardial infarction

by formal analysis. To explore the potential heterogeneity, we performed subgroup analyses and identified study location, mean age and follow-up duration as sources of the variation. Significant heterogeneity between pooled analyses were noted for study location (USA versus Europe, $I^2=66.6\%$, $P=0.084$), mean age (<65 years versus ≥ 65 years, $I^2=66.6\%$, $P=0.084$), follow-up duration (≤ 5 years versus > 5 years, $I^2=66.6\%$, $P=0.084$). Second, each included study had its own adjustment for variables. However, it is impossible for us to apply a uniform adjustment for variables to all studies, because this study was not an individual-level meta-analysis. Third, cystatin C is a novel biomarker, and the best cutoff point is still under debate. Our current meta-analysis does not solve this issue. Despite these limitations, our findings point out new direction for future research. We suggest that further investigation should be performed to clarify whether measurement of cystatin C can usefully reduce the myocardial infarction beyond established predictors already in clinical use.

Conclusion

This meta-analysis showed that cystatin C is strongly and independently associated with subsequent risk of myocardial infarction. Further investigation is warranted to clarify whether measurement of cystatin C can usefully reduce the myocardial infarction beyond established predictors already in clinical use.

Disclosure of conflict of interest

None.
