ABSTRACT

The efficacy of azacitidine in patients with anemia and with lower-risk myelodysplastic syndromes, if relapsing after or resistant to erythropoietic stimulating agents, and the benefit of combining these agents to azacitidine in this setting are not well known. We prospectively compared the outcomes of patients, all of them having the characteristics of this subset of lower-risk myelodysplastic syndrome, if randomly treated with azacitidine alone or azacitidine combined with epoetin- β . High-resolution cytogenetics and gene mutation analysis were performed at entry. The primary study endpoint was the achievement of red blood cell transfusion independence after six cycles. Ninety-eight patients were randomised (49 in each arm). Median age was 72 years. In an intention to treat analysis, transfusion independence was obtained after 6 cycles in 16.3% versus 14.3% of patients in the azacitidine and azacitidine plus epoetin- β arms, respectively ($P=1.00$). Overall erythroid response rate (minor and major responses according to IWG 2000 criteria) was 34.7% vs. 24.5% in the azacitidine and azacitidine plus epoetin- β arms, respectively ($P=0.38$). Mutations of the *SF3B1* gene were the only ones associated with a significant erythroid response, 29/59 (49%) versus 6/27 (22%) in *SF3B1* mutated and unmutated patients, respectively, $P=0.02$. Detection of at least one "epigenetic mutation" and of an abnormal single nucleotide polymorphism array profile were the only factors associated with significantly poorer overall survival by multivariate analysis. The transfusion independence rate observed with azacitidine in this lower-risk population, but resistant to erythropoietic stimulating agents, was lower than expected, with no observed benefit of added epoetin, (*clinicaltrials.gov* identifier: 01015352).

Introduction

Anemia is the most common cytopenia in lower-risk [i.e. low- or intermediate-1 risk by the International Prognostic Scoring System (IPSS)] myelodysplastic syndrome (MDS). First-line treatment of anemia in lower risk MDS (LR-MDS), with the exception of cases with chromosomal deletion 5q (del 5q) that respond better to lenalidomide, generally consists of erythropoietic stimulating agents (ESA), which yield an erythroid response in about 40% to 50% of patients, with a median response duration of about 24 months.¹⁻³ Second-line treatments to avoid anemia recurrence and regular RBC transfusions include: (i) hypomethylating agents (HMA),^{4,6} approved in this context in several countries, (ii) lenalidomide, yielding about 25% of erythroid responses,⁷ but not approved in the absence of del 5q, and (iii) investigational agents.

Among HMA, azacitidine (AZA) at a standard daily dose of 75mg/m² for 7 days, every 28 days, significantly reduces transfusion dependence, decreases the risk of transformation to acute myeloid leukemia (AML), and improves quality of life (QOL) in higher-risk MDS (i.e. intermediate-2 or high IPSS risk MDS).^{5,6} In lower-risk MDS, AZA using 5 or 7 day regimens has been reported to yield RBC transfusion independence (RBC-TI) in 30–40% of LR-MDS,⁸ although lower response rates to AZA were recently reported in Europe in compassionate use programs^{9,10} and in a prospective trial.¹¹ In a recent report of preliminary results of a 3-day only administration of either AZA or decitabine in 83 evaluable LR-MDS patients, overall response was 61%, but RBC-TI was only 24% in the 38 transfusion dependent patients.¹²

In those studies, the resistance of anemia to ESA was not always documented, and the use of AZA has not been prospectively tested in LR-MDS patients selected for their resistance to ESA, an important subset of LR-MDS in daily practice. In addition, the impact of recently described acquired genetic abnormalities in response to AZA in LR-MDS with anemia has not been studied prospectively. Finally, whether the addition of ESA to AZA is beneficial to those patients, as it is in our experience with lenalidomide,¹³ has only recently been studied in a small cohort.¹¹ In a previous retrospective work, our group had indeed suggested a possible benefit (higher transfusion independence rate and better overall survival) of adding ESA to AZA in higher-risk MDS.¹⁴

To address those issues, the GFM designed a phase II randomized clinical trial which compared AZA (using a 5-day monthly schedule) and AZA plus an ESA, in RBC transfusion dependent LR-MDS patients resistant to high-dose ESA.

Methods

Patient Eligibility

Inclusion criteria were: (i) MDS according to WHO criteria or chronic myelomonocytic leukemia (CMML) with WBC < 13 G/L, (ii) age \geq 18 years, (iii) low- or intermediate-1 risk MDS according to IPSS, (iv) resistance to or relapse after at least 12 weeks of high dose ESA (\geq 60 000 U/w for epoetin- α or epoetin- β and \geq 300 μ g/w for darbepoetin), (v) transfusion dependence of at least 4 RBC units/8 weeks, calculated over the previous 16 weeks, and (vi) ECOG-PS score \leq 2.

Exclusion criteria are listed in the *Online Supplementary Information*. This trial was registered in both the EudraCT (2008-004541-29) and the Clinical trial databases (GFMZAzaEpo-2008-1 trial, *clinicaltrials.gov* identifier: 01015352) and was approved by an ethics committee (CPP Ile de France, Aulnay sous Bois) and L'Agence Nationale de Sécurité des Médicaments (ANSM), according to French regulations and in accordance with the Declaration of Helsinki. Each patient provided written informed consent.

Treatment regimen

Patients were randomly assigned to receive either AZA alone (75 mg/m²/d) injected subcutaneously (sc) for 5 days every 28 days, or AZA plus epoetin- β 60 000 U/w sc. Response was assessed after the 4th and 6th cycles of treatment, according to IWG 2000 and IWG 2006 erythroid response (HI-E) criteria. Responders could receive additional cycles, using the same treatment schedule of AZA+/-epoetin- β for a maximum of 18 cycles or until relapse.

Conventional cytogenetic and SNP-A karyotyping

Cytogenetic R-banding analysis was performed on diagnostic bone marrow samples using standard methods. Patient genomic DNA extracted from bone marrow or blood mononuclear cells was processed and hybridized to Genome-Wide Human SNP 6.0 arrays (Affymetrix, Santa Clara, CA, USA) according to the manufacturers' instructions¹⁵ (See *Online Supplementary Information for further details*).

Mutational analysis

At study entry, known or putative mutational gene targets in MDS were examined for mutations using massively parallel sequencing. See *Online Supplementary Information* and *Online Supplementary Table S1 and S3* for further details.

Response criteria

Erythroid response was evaluated after 4 and 6 cycles of AZA, according to IWG 2000¹⁶ and IWG 2006 criteria.¹⁷ RBC-TI was defined as no need for red blood cell transfusions (performed at a Hb level of less than 9 g/dl), with a stable hemoglobin level \geq 9 g/dl lasting for at least 8 weeks. Safety was evaluated by monitoring and recording of adverse events.

Endpoints

The primary endpoint was the achievement of RBC-TI after 6 cycles (major erythroid response HI-E according to IWG 2000). Secondary endpoints were minor and major response according to IWG 2000 criteria and response according to IWG 2006 criteria after 4 and 6 cycles, response duration, overall survival, IPSS progression-free survival, and toxicity.

Sample size justification and statistical analysis

Sample size computation was based on the primary endpoint, assuming a response rate of 40% and 70% in the AZA and AZA plus EPO arms, respectively, based on previously published findings with AZA alone in lower-risk MDS. With type I and type II error rates fixed at 0.05 and 0.20, respectively, a minimum of 49 patients had to be enrolled in each randomized arm, based on a two-sided χ^2 test with Yates continuity correction. (See *Online Supplementary Information* for statistical analysis).

Results

Baseline Patient characteristics (Table 1)

Ninety-eight patients were enrolled between February 2009 and November 2010 in 22 centers (listed in the *Online*

Supplementary Information), including 68 males and 30 females. Forty-nine were randomized in the AZA arm and 49 in the AZA+EPO arm. Median age was 72 years [Interquartile range (IQR) : 65-78]. Diagnosis according to the WHO 2008 classification was RA in 6 patients (6%), RARS in 41 (42%), RCMD in 14 (14%), RCMD-RS in 17 (17%), RAEB-1 in 12 (12%), CMML in 7 (7 %) and MDS-U in 1 (1%). The median interval from MDS diagnosis to inclusion was 37.3 months [IQR : 22.8-59]. IPSS was low in 38 and int-1 in 59 patients (not available in 1 patient with previously normal cytogenetics, due to failed cytogenetics at study entry). Cytogenetics, according to IPSS, were favorable in 77 patients, intermediate in 18, unfavorable in 2 patients, and a failure at study entry in 1. According to the revised IPSS, 1 patient had very low-risk MDS, 77 patients had low-risk and 14 patients had intermediate-risk MDS (6 patients were missing data). The median number of RBC units received in the 8 weeks preceding inclusion were 6 [6-8] and 6 [4-8] in the AZA and AZA+EPO arms, respectively, and the median serum ferritin levels were 1432 [1017-1928] and 1512 [1003-2130] µg/L, in the AZA and AZA+EPO arms, respectively, as expected in such a transfusion dependent lower-risk population, with a median time from MDS diagnosis to study entry of 37 months. As shown in Table 1, no imbalance for baseline patient characteristics was observed between the 2 arms. Apart from ESA, no patient had received any disease-related treatment other than RBC transfusions.

Conventional cytogenetics and SNP array karyotyping

A SNP array karyotype was available in 79 of the 98 enrolled patients (Table 1). Overall, 33 (43%) of these 79 patients had at least one genomic abnormality detected by SNP-A, including 14 patients with favorable karyotype, 16 with intermediate karyotype, 2 with unfavorable karyotype and 1 failure. SNP array karyotype detected 79 CNA (49 losses/30 gains) and 9 UPD. Details of SNP-A lesions are provided in the *Online Supplementary Table S2*.

Mutation analysis

Sequencing was performed in 90/98 patients, of whom 75 (83%) had one or more mutations (Figure 1). Among 17 genes with detected mutations, only 6 were found mutated in more than 3 patients, namely *SF3B1*, *TET2*, *DNMT3A*, *ASXL1*, *JAK2* and *U2AF1* with mutations detected in 59/86, 29/87, 12/86, 5/89, 3/87 and 4/90 patients, respectively. The median number of gene mutations was 1 (range 0-3). In a single patient in this cohort, a *TP53* mutation was detected and associated to complex cytogenetics.

Treatment received

The median number of cycles administered was 6 [6-10] in the AZA arm, and 6.5 [5-9] in the AZA+EPO arm. Forty-six patients (93.9%) in the AZA arm and 41 patients (83.7%) in the AZA+EPO arm received at least 4 cycles. Seven and 17 patients did not receive the planned 6 cycles in the AZA and AZA+EPO arm, respectively. Four patients did not receive any treatment due to: sudden death (n=1), screening failure (n=1), the patient's decision (n=1), or the diagnosis of a solid tumor just after screening (n=1). The reasons for treatment interruption before 6 cycles were: the patient's decision (n=6), the investigator's decision (n=1), an absence of response after 4 cycles (n=2), AML

transformation (n=2), persistent cytopenia (n=1), documented infection (n=2), febrile neutropenia (n=1), other azacitidine side effects (n=3), and the discovery of pancreatic cancer (n=1). One allogeneic stem cell transplantation was performed in an early responder (Figure 2). With a median follow-up of 47.3 months, 9 (18.4%) and 7 (14.3%) patients had received at least 18 cycles in the AZA and AZA+EPO arms, respectively.

Primary Endpoint (Table 2)

In an intention to treat analysis, RBC-TI after 6 cycles (major HI-E according to IWG 2000) was achieved in 8 patients (16.3%, 95%CI: [7.3-29.7]) in the AZA arm and in 7 patients (14.3%, 95%CI: [5.9-27.2]) in the AZA+EPO arm ($P=1.0$). No predefined factors (including treatment arm, WHO subtype, cytogenetics, IPSS, presence of at least one SNP array abnormality or of one of the 6 most frequent gene mutations) were significantly associated with RBC-TI.

Figure 1. Distribution of mutations according to WHO diagnosis.

Secondary Endpoints (Table 2)

RBC-TI rate after 4 cycles was achieved in 5 patients (10.2%, 95%CI: [3.4-22.2]) in the AZA arm and in 7 patients (14.3%, 95%CI: [5.9-27.2]) in the AZA+EPO arm ($P=0.76$). Overall response rate (minor and major response) according to IWG 2000 criteria after 4 cycles was achieved in 18 patients (36.7%, 95%CI: [23.4-51.7]) in the AZA arm and in 15 patients (30.6%, 95%CI: [18.3-45.4]) in the AZA+EPO arm ($P=0.67$). Overall response rate (minor and major response) according to IWG 2000 after 6 cycles was achieved in 17 patients (34.7%, 95%CI: [21.7-49.6]) in the AZA arm and in 12 patients (24.5%, 95%CI: [13.3-38.9]) in the AZA+EPO arm ($P=0.38$).

According to IWG 2006 criteria, HI-E was achieved after 4 cycles in 14 patients (28.6%, 95%CI: [16.6-43.3]) in the AZA arm and in 14 patients (28.6%, 95%CI: [16.6-43.3]) in the AZA+EPO arm ($P=1.0$). After 6 cycles, HI-E was achieved in 15 patients (30.6%, 95%CI: [18.3-45.4]) in the AZA arm and in 13 patients (26.5%, 95%CI: [14.9-41.1]) in the AZA+EPO arm ($P=0.82$). An overall response according to IWG 2006 criteria was achieved in 21 patients (42.9% with 95%CI [28.8-57.8]) in the AZA arm versus 17 patients (34.7% with 95%CI: [21.7-49.6]) in the AZA+EPO arm ($P=0.53$). After 4 cycles, in the whole cohort, HI-P according to IWG 2006 criteria was achieved in 6/20 (30%) patients with thrombocytopenia. HI-N was achieved in 9/15 (60%) patients with neutropenia.

SF3B1 mutation was associated with the erythroid response according to IWG 2006 criteria, with 29/59 (49%) responses observed in *SF3B1* mutated versus 6/27 (22%) in *SF3B1* unmutated patients ($P=0.02$). The median number of RBC units received in the 8 weeks preceding study entry was significantly higher in responders (7 [6-9.8]) than in non-responders (6 [4-8]) ($P=0.017$), while no other prognostic factors of overall response were observed (Table 3). In the multivariate analysis, RBC transfusion burden, in the 8 weeks preceding inclusion ($P=0.041$) and *SF3B1* ($P=0.022$), were associated with the erythroid response.

In the 38 responders according to IWG 2006 criteria, median response duration was 7.6 months (95%CI: [4.4-16.8]) in the AZA arm and 9.7 months (95%CI: [5.0-21.2])

in the AZA plus EPO arm ($P=0.53$). (Figure 3). The median duration of disease, using our primary endpoint, i.e. RBC-TI (or major IWG 2000 criteria), was 10.5 months (95%CI: [5.9-NA]) in the AZA arm and 16.6 months (95%CI: [13.8-NA]) in the AZA plus EPO arm ($P=0.15$).

Survival

With a median follow-up of 47.3 months [IQR: 24.4-65], the 3-year overall survival was 72.1% (95%CI: [60.3-86.2]) in the AZA arm vs. 66.8% (95%CI: [54.3-82.]) in the AZA+ EPO arm, respectively ($P=0.93$) (Figure 4). In univariate analyses, factors significantly associated with poorer overall survival were: any SNP array abnormality ($P=0.013$), *ASXL1* mutation ($P=0.01$), and the presence of at least one "epigenetic mutation", (defined as any mutation observed in the *TET2*, *DNMT3A*, *ASXL1*, *IDH2*, *KDM6A*, and *EZH2* genes) ($P=0.022$). In the 8 weeks preceding inclusion, WHO diagnosis, IPSS, IPSS cytogenetics, RBC transfusion burden and serum ferritin levels had no significant impact on overall survival. Early ESA failure, defined by primary ESA resistance or relapse within 6 months of response,¹⁸ was not associated with survival in this cohort ($P=0.63$).

In the multivariate analysis, only the detection of a SNP array abnormality ($P=0.01$) or of an "epigenetic mutation" ($P=0.02$) were associated with a significantly poorer overall survival.

IPSS progression-free survival

During their time in the study, disease evolution according to IPSS was documented in 18 patients, 6 and 12 of them in the AZA and AZA+EPO arms, respectively. Three-year IPSS progression-free survival was 91.1% (95%CI: [83.6-99.8]) and 72.4% (95%CI: [65.7-90.8]) in the AZA and AZA+EPO arms, respectively ($P=0.12$).

Discussion

In this phase II trial of azacitidine in lower risk-MDS patients, selected for their resistance to an ESA, the overall

response rate after 6 cycles of azacitidine, according to IWG 2000 criteria, was estimated at 34.7% in the AZA arm *versus* 24.5% in the AZA+EPO arm. However, the RBC transfusion independence rate was only 16.3% in the AZA arm and 14.3% in the AZA+ EPO arm, i.e. lower than the 45% and 44% RBC-TI rates previously reported by other groups in unselected lower-risk MDS.^{6,8,12} Explanations for those differences possibly include the fact that our patients had been selected for their resistance to ESA (which was not a prerequisite in most prior studies), and had a minimal RBC transfusion dependency of 4 units in the 8 weeks prior to the study (the median number of RBC units in the 8 weeks prior to study entry was 6 [4-14]). By comparison, in the Lyons *et al.* trial⁸ only 47% of patients were RBC transfusion dependent, and a lower RBC transfusion requirement (less than 2 units/8 weeks) was predictive of RBC-TI achievement with AZA (*Online Supplementary Table S4*). In other studies,^{9,11} which included a higher proportion of transfusion dependent patients, a lower erythroid response rate, ranging from 30% to 40% was also observed.

Another difference with several other series was that most of our patients had anemia as cytopenia. Only 22% of the patients also had thrombocytopenia, compared to 56% in the trial by Lyons *et al.* Therefore, hematologic improvement in other lineages, frequently taken into account in the evaluation of the overall response to azacitidine in other series, was by definition lower in our patients.^{6,8,12}

The addition of ESA in our randomised trial did not significantly improve response rate, contrary to what we

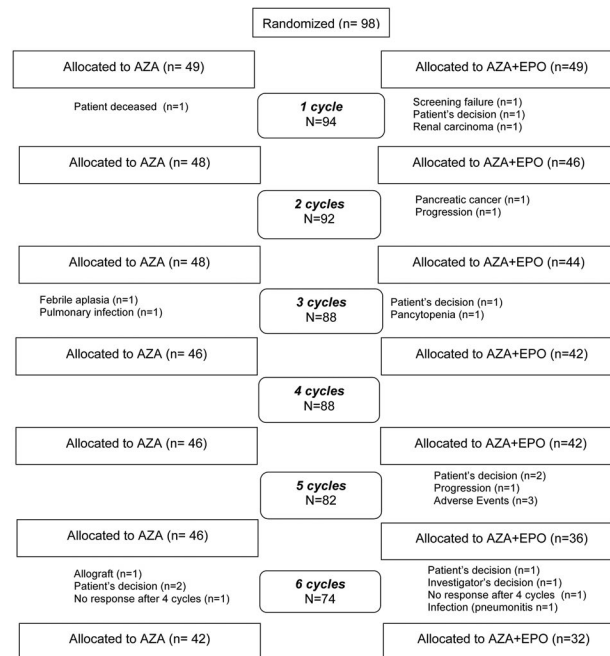

Figure 2. Consort flow diagram.

observed using lenalidomide in lower-risk MDS resistant anemia.¹³ Our group had published that the addition of

EPO to AZA in higher-risk MDS patients improved response rate, but this difference was not associated with better OS.¹⁴ The detection of a *SF3B1* mutation and the median number of RBC transfusions were significant prognostic factors of the response according to IWG 2006 criteria in our study. In the trial by Lyons *et al.*,⁸ the absence of neutropenia and thrombocytopenia, and a baseline transfusion requirement of ≤ 2 RBC units every 8 weeks were predictive of higher RBC TI. In higher-risk

MDS, our group had published that RBC transfusion dependence was a prognostic factor for poorer OS, but not for response to AZA.¹⁹

With prolonged follow-up in all our patients, the median duration of response was relatively short (7.6 months and 9.7 months in the AZA arm and in the AZA plus EPO arm, respectively), but 13.6% and 18.8% of responses were longer than 2 years in the 2 arms, respectively. This result is similar to previous series, where median response

* In the 8 weeks preceding entry.

durations ranging from 511 to 10 months²⁰ were reported (*Online Supplementary Table S4*). Overall survival at 3 years in the present trial was 72.1% and 66.8% in the AZA arm and in the AZA plus EPO arm, respectively. It was similar, but with longer follow-up, than previously reported in a phase II trial with decitabine²¹ and with azacitidine in the Nordic trial,¹¹ where median OS survival was not reached after 14.6 and 30 months, respectively. Recent USA retrospective data reported a median OS of 16 months after HMA failure in lower-risk MDS.²²

Our study was also the first to prospectively study the impact of SNP array and mutational analysis in lower-risk

MDS treated with a HMA. The frequency of mutations in this lower-risk MDS patient cohort was different from that previously published by Bejar *et al.*,²³ with a higher frequency of *SF3B1* mutations (68.6% compared to 22% for Bejar *et al.*), explained by the high proportion of sideroblastic anemias included in our series. *TET2* and *ASXL1* mutations were present in 33.3% and 5.6% of our patients, compared to 23% and 15%, respectively, in Bejar *et al.*'s cohort. The mutation of *ASXL1*, previously associated with an adverse outcome, was found in 5.6% of our patients. The mutation of *TP53* was detected in a single patient in the present study cohort of *de novo* MDS, in con-

trast to other studies^{12,23} in which patients with therapy-related MDS were also analyzed.

In univariate analysis, the presence of a SNPa abnormality, of an *ASXL1* mutation and of any "epigenetic mutation" were significantly associated with poorer survival, whereas only a trend was observed for longer interval from diagnosis of MDS. In multivariate analysis, only the detection of a SNP array abnormality and of at least one "epigenetic mutation" were associated with overall survival. In the lower-risk MDS series of Bejar *et al.*, analyzed irrespective of treatment and adjusted on a lower-risk prognostic system (LR-PSS), only the presence of *EZH2* mutations was predictive of a shorter OS.

Our study also confirmed that SNP array analysis can be of interest in lower-risk MDS, as genomic abnormalities were detected by this technique in 14 patients with normal karyotype. SNP analysis, rarely performed in large series of MDS, when used in a previous series, had allowed for the detection of cytogenetic abnormalities in 74 % of the patients *versus* 44% by conventional banding

studies, and also had prognostic significance.^{24,25} None of those studies, however, had focused on homogeneously treated lower-risk MDS. In the present study, patients with at least one SNPa abnormality had a trend for poorer survival, which reached significance in multivariate analysis, along with the presence of at least one "epigenetic mutation".

In conclusion, a lower than expected overall response rate to azacitidine was observed in this cohort of lower-risk MDS patients, selected for their resistance to ESA. No benefit of the addition of an ESA could be demonstrated in this population. As responders were significantly more likely to be mutated for the *SF3B1* gene, the use of azacitidine remains an available therapeutic option in these patients, often resistant or refractory to ESA alone, until new treatments clearly emerge for this population, such as sotatercept and luspatercept, currently under development. A direct comparison with lenalidomide^{7,13} would be needed to more clearly assess each drug's benefit in ESA resistant lower-risk MDS.
