Abstract

Background—The risk of cardiovascular problems due to diabetes mellitus is highest among older Mexicans, and yet what remains to be determined is the association between muscle weakness and diabetes in this population. Therefore, the purpose of this study was to determine the association between muscle strength and diabetes among Mexican adults greater than 50 years old.

Design—Cross-sectional.

Setting—National sample of households in both urban and rural areas.

Participants—A sub-sample of 1,841 individuals, aged 50 years and older, was included from the 2012 Mexican Health and Aging Study (MHAS).

Measurements—Strength was assessed using a hand-held dynamometer, and the single largest reading from either hand was normalized to body mass (NGS). Conditional inference tree analyses were used to identify sex-specific NGS weakness thresholds. Linear regression was used to examine the association between NGS and HbA1c, and logistic regression was used to assess the

Conflict of Interest Statement:

The author report no conflicts of interest.

association between weakness and risk of diabetes (HbA1c 6.5% [48 mmol/mol]), after controlling for age, sex and waist circumference.

Results—Normalized grip strength was inversely associated with HbA1c (β =-1.56; p<0.001). Optimal sex-specific NGS weakness thresholds to detect diabetes were 0.46 and 0.30 for men and women respectively. Weakness was associated with significantly increased odds of diabetes (OR: 1.69, 95%CI: 1.37-2.10), even after adjusting for age, sex, and waist circumference.

Conclusions—NGS was robustly associated with diabetes and other cardiometabolic risk factors in older Mexicans. This simple screen may serve as a valuable tool to identify adults that are at risk for negative health consequences or early mortality, and that might benefit from lifestyle interventions to reduce risk.

insulin resistance; diabetes; muscle weakness; aging; epidemiology

Introduction

Diabetes is a leading cause of mortality that is estimated to affect over 400 million adults globally,¹ particularly in low- and middle-income countries where more than 80% of diabetes deaths occur ². For example, in Mexico the lifetime risk of diagnosed diabetes is projected to reach 50% by 2050,³ and there is also a high prevalence of impaired glucose tolerance,⁴ and undiagnosed or uncontrolled diabetes.⁵ From 1970 to 2010, Mexican mortality fell by two-fold for individuals aged >50 years (from 33% to 17%), and this has been attributed to expanded health-care infrastructure and access in poorer states.⁶ However, older adults are at increased risk for chronic cardiometabolic diseases such as diabetes, a known driver of both years lived with a disability and disability-adjusted life years in Mexico.⁷ An age-related decline in physical function and deterioration in muscle morphology contribute to exaggerated risk of diabetes, combined with declining mortality levels, have led to an acceleration of lifetime diabetes risk and more years spent with diabetes at the population level. Therefore, the aging Mexican population poses a substantial burden to the country's future healthcare system.

Early screening and promotion efforts for healthy aging among higher-risk populations are vital to mitigate the incidence of diabetes and other preventable comorbidities; thereby curtailing the escalating healthcare costs associated with chronic conditions. There has been an increase in the amount of evidence that highlights the role of muscular strength preservation as a protective factor for cardiometabolic health across populations. Recent investigations⁸⁻¹⁰ have shown that low muscular strength is independently associated with increased odds of the metabolic syndrome and diabetes in adults, and that cut points or centiles¹¹ for low normalized strength may be used to predict increased risk. Moreover, longitudinal data have demonstrated that chronic hyperglycemia¹² and greater fat mass¹³ (i.e., two hallmark risk factors for diabetes) are associated with diminished muscle quality and weakness. There is also mounting evidence that indicates a robust inverse association between low strength and cardiometabolic risk clustering among children and

Page 3

adolescents,¹⁴⁻¹⁶ thus reinforcing the need for early and improved clinical screening strategies across populations. Therefore, the purposes of this study were to examine the independent association between handgrip strength capacity and diabetes in a large sample of aging adults in Mexico, and to identify potential sex-specific weakness thresholds for detection of diabetes.

Research Design and Methods

Study Population

The Mexican Health and Aging Study (MHAS) was designed to prospectively evaluate the impact of disease on the health, function, and mortality of adults over the age of 50 years in a national sample of households in both urban and rural areas of Mexico. The overall goal of the study is to examine the aging process, including the impact of disease and disability in a large representative panel of older Mexicans, as previously described in detail.^{17,18} The MHAS study protocols and instruments were approved by the Institutional Review Board or Ethics Committee of the University of Texas Medical Branch, the Instituto Nacional de Estadistica y Geografia (INEGI) in Mexico, and the Instituto Nacional de Salud Publica (INSP) in Mexico.

Of the 15,723 participants who were interviewed in the 2012 MHAS (survey wave 3), a subsample of 2,086 was selected in order to collect anthropometric measures, blood pressure readings, performance tests, and blood biomarkers. Of these, 1,841 participants had (1) complete demographic and anthropometric data; (2) valid strength data from a handgrip dynamometer; and (3) the necessary blood samples obtained for non-fasting glycohemoglobin determination.

Anthropometric Factors

Each participant wore light clothing and no shoes while being weighed on a digital Toledo scale (Mettler-Toledo International, Inc., Columbus, OH). Height was measured using a fixed stadiometer. Body mass index (BMI) was calculated as weight in kilograms divided by height in meters squared (kg/m²). Standard categories were applied to determine if each participant was normal weight (18.5-24.9 kg/m²), overweight (25.0-29.9 kg/m²), or obese (30.0 kg/m^2).¹⁹ Individuals with BMI <18.5 kg/m² were excluded (n=15), due to the known association between underweight status and diabetes risk in older adults.²⁰ Waist circumference was measured to the nearest 0.1 cm at the level of the iliac crest, and used in the analyses as a continuous variable.

Cardiometabolic Parameters

Participants were tested on routine cardiometabolic parameters. Resting systolic and diastolic blood pressures were measured twice with a mercury sphygmomanometer by trained staff. Non-fasting measures of total cholesterol, HDL-cholesterol, thyroid-stimulating hormone, serum 25-Hydroxyvitamin D, and C-reactive protein concentrations were also measured. Non-fasting serum measures of glycohemoglobin (%) were included as a diagnostic test for diabetes, which reflects average plasma glucose for the previous ~3 months. HbA1c was measured using A1cNow assay, a method that is National

Glycohemoglobin Standardization Program certified. Participant diabetes status was based on elevated non-fasting HbA_{1c} (6.5% [48 mmol/mol]), which reflects uncontrolled diabetes 21 .

Exposure Variable

Grip Strength

Strength was assessed using a hydraulic handgrip dynamometer (Jamar Hydraulic Dynamometer, model 5030J1; JA Preston Corp., Clifton, NJ). A trained examiner explained and demonstrated the protocol to the participant, then adjusted the grip size of the dynamometer to the participant's dominant hand size, and asked the participant to squeeze the dynamometer for a practice trial. Thereafter, the participant was instructed to start the test with his/her dominant hand, and was asked to squeeze the dynamometer with maximal effort, exhaling while squeezing. The test was then repeated with the opposite hand. Each hand was tested two times, alternating hands between trials with a 60-second rest between measurements on the same hand. The grip test was performed in the standing position unless the participant was physically limited. Participants were excluded from this component if they were unable to hold the dynamometer and perform strength testing with both hands. Participants who had surgery on either hand or wrist in the last three months were not tested on that particular hand. Since the link between muscle strength and both physical function and chronic health is mediated by the proportion of strength relative to body mass, grip

strength was normalized (NGS) as strength per body mass (i.e., $\left(\frac{Grip}{Body} \frac{Strength}{Mass} \frac{(kg)}{(kg)}\right)$).

Statistical Analysis—All statistical analyses were conducted using SAS 9.3 (SAS Institute, Cary, NC) and R version 3.1.2 (R Foundation for Statistical Computing, Vienna, Austria). Descriptive characteristics and cardiometabolic profiles are provided as means, standard errors, and percentages. Differences in these characteristics across strength categories were tested using linear and logistic regression for continuous and categorical variables respectively, after creating appropriate categories and dummy coding for each. A similar strategy was used to test differences for outcomes between men and women.

Threshold Analyses: Conditional inference tree analyses were used to determine risk thresholds of NGS in differentiating the risk for diabetes among all participants. Unlike a recent study in older adults that used classification and regression tree (CART) analysis to identify cut points for weakness,²² we chose not to incorporate this method because it tends to overfit. The conditional inference tree method recursively partitions participants into mutually exclusive groups defined by predictor cut points, grouping together participants with similar outcome probabilities.²³ However, in contrast with CART, it utilizes a formal statistical framework to evaluate the recursive partitioning, taking into account both the distributional properties of the measures and multiple comparison between groups. This technique is also free of modeling assumptions, which allows for optimal concurrent validity, by identifying those cut points with the strongest association with diabetes. Moreover, it does not require an *a priori* specified number of cut points, and thus it can provide more than a single threshold to predict the outcome. The analysis was conducted using R software with the party package.²³

To assess the odds of diabetes in the entire sample, we utilized the multivariate logistic regression modeling approach. Known risk factors including gender, age, waist circumference, and NGS (both continuous [per 0.10 variation in strength relative to body mass] and dichotomous for "weakness") were adjusted in the model. The logistic regression model with the highest Akaike information criterion (AIC) was retained as the final model.

Results

Descriptive and cardiometabolic characteristics are presented as means, standard errors, and percentages across sexes in Table 1. Men were stronger than women in both absolute and normalized grip strength capacity (p<0.001). Prevalence of obesity, abdominal obesity, diabetes status, high CRP, and vitamin D deficiency were all significantly greater in Mexican women as compared to men; whereas, prevalence of low HDL and hypertension were higher among Mexican men.

Threshold Analysis

Conditional inference trees predicting diabetes confirmed different low strength thresholds for men and women. Figure 1 provides results for the primary definitions. The cutoff identified in men was based on having normalized grip strength less than or equal to 0.46 (i.e., grip strength in kg $[0.46 \times \text{body mass in kg}]$) versus greater than 0.46. Among women the identified NGS cutoff was based on having normalized grip strength less than or equal to 0.30 versus greater than 0.30.

In both men and women, prevalence of obesity and abdominal obesity were significantly higher among individuals in the weak NGS category (Table 2). Weak individuals also had significantly higher prevalences of vitamin D deficiency (women only), elevated CRP (both men and women), and hypertension (women only) (all p<0.01). Diabetes prevalence, according to elevated HbA_{1c} (6.5% [48 mmol/mol]), was significantly higher among weak versus strong individuals and was 39.3% vs. 25.3% for men, and 51.0% vs, 31.5% for women, for weak and strong NGS respectively.

In the adjusted models (Table 3), women were at higher odds of having diabetes than men (<0.001), and waist circumference was positively associated with diabetes. Moreover, for every 0.10 decrement in normalized strength, there was a 1.22 times increased odds for diabetes (p<0.001). Weakness was associated with significantly increased odds of diabetes (OR: 1.69, 95% CI: 1.37-2.10), even after adjusting for age, sex, and waist circumference.

Discussion

The principal finding of this study was that normalized grip strength is significantly associated with diabetes in older Mexican men and women. Specifically, for every 0.1 decrement in strength-to-body mass-ratio, there was a 22% increased adjusted odds of diabetes. Furthermore, when using sex-specific NGS thresholds, weak men and women both had significantly greater diabetes prevelance and higher prevalences of certain cardiometabolic abnormalities (e.g., abdominal obesity, vitamin D deficiency, elevated CRP, and hypertension) compared to their strong counterparts. These findings indicate that hand

grip strength is a simple and inexpensive technique that identifies risk for diabetes and other cardiometabolic determinates of health in older Mexican adults.

Global life expectancy has increased in recent years; and yet, obesity is also expected to increase by 12% among older adults by the year 2030.²⁴. Obesity has remained highly prevelant in older Mexican men and women, putting them at elevated risk for chronic cardiometabolic diseases such as diabetes -- a leading cause of early mortality in Mexico.^{2,25,26} The present investigation identified 28.0% of men and 43.2% of women as obese, and 33.0% of men and 38.3% of women as diabetic. These results differ slightly from an investigation by Rodríguez-Saldaña et al.,²⁷ who showed non-diabetics were more obese than persons with diabetes, and that diabetes was more common in men than women. Comparisons across studies are difficult however, as different criteria were used to diagnose diabetes, participants were aged at least 65 years, and participants were only residing in retirement housing in Mexico City. Older Mexican adults are known to have less muscle mass and greater visceral adiposity than non-Hispanic Whites and Blacks in the U.S., suggesting that behavioral factors associated with these age-related changes may mediate the association between functional declines and risk for metabolic disease.²⁸ Indeed, we found that diabetes prevalence was 14.0% and 19.5% greater in weak men and women compared to their stronger counterparts, respectively. Moreover, a recent study by Kumar et al.²⁹ demonstrated that older obese Mexicans are at a greater risk for physical disability than their non-obese counterparts. Both obesity and diabetes are predictors of functional declines in older adults;³⁰ however, the simultaneus loss of muscle and increase in adiposity with age also contributes to reduced functional performance and increased risk of diabetes. Therefore, these are highly interrelated factors that contribute to diabetes prevalence and weakness, making it difficult to fully understand the direction of causation. Considering that persons with diminished functional performance are at greater risk for developing diabetes, improved strategies to reduce diabetes risk in older Mexican populations should be emphasized.³¹ These findings underscore the consequences of sarcopenic obesity, particularly as a primary contributer to diabetes risk in older adults.^{32,33}

Sarcopenic obesity is associated with many negative chronic cardiometabolic determinates of health, including abdominal obesity, elevated inflammatory markers, and hypertension.³⁴ Older adults are at particularly elevated risk for sarcopenic obesity, as age-related decrements in muscle size and physical activity become accelerated.^{34,35} Our results demonstrate that weak men and women were more likely to be obese, had higher levels of central obesity, and were at higher risk for cardiovascular disease from elevated CRP levels. Greater vitamin D deficiency and hypertension were more prevalent only in weak women. These results align with other studies suggesting that central obesity, inflammatory markers, vitamin D deficiency, and hypertension are greater in older adults that are weaker.^{36,37} These findings confirm that older Mexicans are at similar risk for developing chronic cardiometabolic diseases associated with muscle weakness.

Hand grip strength has been recognized as a valid technique to predict risk of disability, which is significantly associated with diabetes in older Mexican Americans in the U.S..³⁸ Another recent study that used age- and sex-specific NGS cuttoffs from 4,066 U.S. adults, revealed that for every 0.5 decrement in NGS, there was a 26% increased odds of diabetes.⁹

By comparison, the present investigation included 1,841 Mexican participants aged at least 50 years and found for every 0.1 decrement in NGS, there was a 22% increased odds of diabetes. A 5-year prospective cohort study by Al Snih et al. ³⁹ determined 2,488 older Mexican adults were more at risk for mortality when hand grip strength was low. Considering that diabetes is a leading cause of mortality in Mexico, the association between hand grip strength as a determinent of muscle weakness, sarcopenic obesity, diabetes, and mortality should be further studied.² This investigation also demonstrated that waist circumference was positively associated with diabetes and women had higher odds of having diabetes than men. These results concur with previous studies that have identified central obesity as a risk factor for diabetes and that women have more fat mass and lower absolute and relative strength than men, putting older Mexican women at greater risk for diabetes.^{34,40}

This study has a number of strengths that extend the current body of literature on diabetes prevention. Analyses were conducted on a large number of participants who have been followed several years. To our knowledge, this is the first study to investigate the role that muscle weakness plays on diabetes prevalence in older Mexicans. The threshold modeling technique used in this investigation identified two strength cutpoints and two respective risk categories, which may be incorporated into a clinical setting for screening older Mexicans that are at risk for diabetes. Also, hand grip strength was normalized to body mass, making comparisons across body sizes possible. Despite these strengths, some limitations of the present study should be noted. Physical activity and nutritional data were not examined, and thus future efforts should seek to determine how these variables mediate the association between hand grip strength and diabetes. Further, as with all cross-sectional studies, a limitation of this investigation is the inability to unravel the direction of causation. Whether lower NGS "cause" an elevated risk for diabetes in older Mexicans, or if diabetes-related musculoskeletal conditions (e.g., neuropathy, diabetic cheiroarthropathy, flexor tenosynovitis, etc.) themselves, are a cause of diminished muscle function, is an interesting and complex topic. Lastly, other tests, such as quadriceps strength were unavailable, making comparisons between hand grip strength and other tests of muscle weakness unknown. Future investigations should explore the association between hand grip strength on chronic cardiometabolic diseases in other ethnicities and to examine the attributable risks of physical disability status and hand grip strength on incident diabetes in older adults.

Conclusion

Individuals with low NGS had a greater prevalence of diabetes and other cardiometabolic risk factors as compared to their strong counterparts. The odds of prevalent diabetes increased as NGS decreased. Health professionals should encourage older Mexican adults, and especially women, to engage in physical activities that help preserve or improve muscle strength in an effort to prevent chronic cardiometabolic diseases. NGS should also be used to monitor and assess muscle weakness in older Mexicans and other older populations.
