Abstract

Background: The systemic antimicrobial prophylaxis is the standard treatment in the prevention of osteomyelitis after open fractures, with topical application of antimicrobials as an alternative due to their high concentrations at the site of the fracture, low systemic concentrations and fewer side effects.

Objectives: This study aimed to evaluate the effectiveness of prophylaxis of osteomyelitis through experimental model of open fractures with the use of chitosan films, whether or not impregnated with ciprofloxacin.

Materials and Methods: In this experimental study, 24 Holtzman rats were distributed into 4 groups of 6 rats each. The CT (control of treatment) group: an open fracture model treated with systemic antimicrobial; the IC (infection control) group: an open fracture untreated model; the C (chitosan) group: an open fracture model treated using a chitosan film; and the CA (chitosan with antimicrobial) group: an open fracture model treated using a chitosan film impregnated with antimicrobial. After 3 weeks the animals were killed by an overdose of anesthetic, and a fragment osseous was removed for histological and microbiological analysis. The comparisons between the groups considered significant values of $P \leq 0.05$.

Results: In cultures of the CT group, there was less bacterial growth compared to the results of the cultures of the IC ($P = 0.005$), C ($P = 0.005$) and CA ($P = 0.009$) groups. The inflammation was lower in the CT group compared to the IC ($P = 0.014$), C ($P = 0.001$) and CA ($P = 0.007$) groups.

Conclusions: In this experimental model of open fracture, the chitosan film pure or impregnated with ciprofloxacin was not effective in the prophylaxis of osteomyelitis.

Keywords: Open Fracture, Prophylaxis, Osteomyelitis, Chitosan, Ciprofloxacin

1. Background

The incidence of open fractures in long bones is estimated 11.5 in 100.000 people (1); the purpose of the treatment is to prevent infection, promote fracture healing and restore function (2). Despite treatment, about 10% to 50% will progress to osteomyelitis (3-5). Systemic prophylaxis is the standard for the treatment of open fractures since 1974, and its benefit was confirmed by a Cochrane review, where it was observed that the use of antibiotics after open fractures reduces the risk of infection by 59% (6).

Over the last decade, it has increased trend for the

application of topical antimicrobial prophylaxis of osteomyelitis secondary to open fractures (7). This method provides high concentration of an antimicrobial at the site of the fracture with low systemic concentration, reducing the risk of side effects (7). The most frequently used for this purpose, is the polymethylmethacrylate (PMMA). An alternative is chitosan, a biological product derived from the chitin of shellfish, bioabsorbable (8), bactericidal (9) and allowing storage and gradual release of drugs (10), including antimicrobials. Dehydrated chitosan films have the ability to rapidly rehydrate and absorb drugs (11). Manipulation of the properties of this film during production

may improve the local distribution of assisting in the prophylaxis of antimicrobial infections (10, 11).

2. Objectives

The aim of this study was to evaluate the effectiveness of prophylaxis of osteomyelitis secondary to open fractures in an experimental model with chitosan films, whether or not impregnated with ciprofloxacin comparing with standard treatment with antibiotic prophylaxis.

3. Materials and Methods

Between January and August 2015, 24 males Holtzman rats selected from Universidade federal de Minas Gerais (UFMG), with approximately three months of life and weighing 261.95 ± 20.82 were divided into 4 groups:

The control treatment (CT) group (n = 6): open fracture treated with systemic antimicrobial.

The infection control (IC) group (n = 6): open fracture without treatment.

The chitosan (C) group (n = 6): open fracture treated with a pure chitosan film.

The chitosan with antimicrobial (CA) group (n = 6): open fracture treated with a chitosan film impregnated with ciprofloxacin.

The rats were placed in cages with three animals of the same group at the vivarium of the UFMG Medical School with water and rat food, temperature control, ventilation and natural day-night cycle under daily monitoring by the researchers. The animals were anesthetized and maintained under sedation by intraperitoneal injection of ketamine and xylazine at doses of 15 mg/kg and 60 mg/kg, respectively. The femoral fracture of the left hind leg of the animal was performed using special equipment that makes the fracture with a similar pattern in all the animals (Figure 1). After the trichotomy on the left hand, antisepsis was done with polivinilpirrolidona (Povidine® - Johnson & Johnson, Brazil) in degerming solution, followed by an alcoholic solution. The protection of the area with sterile drapes was done, keeping exposed the paw to be operated. After sterile surgical scrub was done, an incision was made longitudinal in the middle third of the left thigh and dissection by planes to exposure the femoral fracture. The intramedullary fixation of the fracture was performed using a needle aspiration 40×1.2 mm and 0.1 milliliters of inoculated suspension of *Staphylococcus aureus* (UFMG Central Lab) in concentration of 10 CFU/mL set by McFarland (12), applied in the bed of the fracture. The wound was sutured with nonabsorbable monofilament nylon 5-0 (Mononylon Ethicon®).

Figure 1. Special Equipment That Was Used to Make the Fracture

In the C, and CA groups, the sterile chitosan film was placed in the bed of the fracture with dimensions of 0.5 cm \times 0.5 cm pure and impregnated with ciprofloxacin 10% (Shaanxi New Leader Trading Co. Ltd. China.) respectively, followed by the closure of the wound in previous groups. After surgery the animals were kept in the vivarium, with water and food. Analgesia was performed through solution of meloxicam (Mobic® - Boehringer Ingelheim Brazil Ltda, SP, Brazil) with a dose of 0.2 mg/kg subcutaneously on the immediate postoperative period.

The CT group was treated with ciprofloxacin (Ciprodez® - Bio -Vet S/A, SP, Brazil) intraperitoneal dose of 2.5 mg/kg/day, for three days and the IC group did not receive any treatment to open fracture. The wound was daily evaluated and the sutures were removed 10 days after the surgery. After three weeks, the animals were killed through

anesthetic overdose under aseptic conditions, the femur was removed and the material submitted to qualitative culture and histological analysis.

The cultures were performed on blood agar and considered positive when showed bacterial growth in 72 hours with the same microorganism inoculated in the medullary bed (*Staphylococcus aureus*). In all groups qualitative cultures were performed in the suspension with *S. aureus* to ensure the presence of bacteria in the fracture of the femur of the studied animals. All *S. aureus* isolated were submitted to antibiogram to verify sensitivity to ciprofloxacin.

For histological examination, the samples were stained with hematoxylin-eosin and evaluated by the same pathologist in conventional optical microscopy researching osteomyelitis in activity. Histological classification was performed based on data for intraosseous acute inflammation, intraosseous chronic inflammation, periosteal inflammation and bone necrosis using the system of Smeltzer et al. (13). Each parameter was graded on a five-point scale (zero to four) and the sum of respective histological parameters calculated as a total histological score.

The study was approved by the ethics committee of animal use at Universidade federal de Minas Gerais (UFMG), under protocol 240/2011.

3.1. Data Analysis

The sample size was calculated using Minitab® version 14.1 software (Minitab Inc., PA, USA), and $\alpha = 0.05$, test power > 0.80 and maximum deviation between the results equal to the average, resulting in six sample animals per group. The values of mean and standard deviation were established after performing a pilot project.

The data were analyzed by the software EPI inform 7.1.2.0 for Windows® (Atlanta, USA) using Fisher's exact test to compare the qualitative variables and the Mann-Whitney test to compare quantitative variables. Weight difference between groups was detected by the Kruskal-Wallis test. Differences were considered significant with $P < 0.05$.

4. Results

There was no significant difference in the average weight of the animals between the groups (Table 1). A significant difference was observed between the cultures of the CT group compared with the cultures of the IC, C and CA groups (Table 2). The antibiogram showed sensitivity of the isolated bacteria to ciprofloxacin. Histological analysis showed a significant difference in the total points of animals undergoing treatment with systemic antibiotic prophylaxis (the CT group) compared to the other groups. It

was also seen that when parameters of this scoring system were evaluated in isolation, the biggest difference between the animals of the group treated with antibiotic prophylaxis (the CT group) and the others was the degree of intraosseous chronic inflammation. The comparison of histological results is summarized in Table 3.

Table 1. Animals Weight in the Different Groups

Group	Animals Weight		
	Mean (g)	SD (g)	P Value
CT	252,50	20,29	-
IC	265,83	16,55	0,44
C	259,50	20,40	0,84
CA	270,00	26,13	0,56

Abbreviations: SD, standard deviation; g, gram.

Table 2. Results of Qualitative Cultures in the Different Groups

Group	Culture Results		P Value
	Positive	Negative	
CT	0	6	-
IC	5	1	0.005
C	6	0	0.009
CA	5	1	0.005

5. Discussion

The most important finding of this study was that a chitosan film impregnated with ciprofloxacin can be used for local delivery of antibiotics in open fractures wound; however, the concentrations of 10% of ciprofloxacin is not effective to prevent the development of infection in a rat model of open fracture.

The principles in the treatment of open fractures are the surgical emergency treatment, appropriate antibiotic therapy, adequate irrigation and debridement, stabilization of the fracture, wound healing and rehabilitation. Infection is the most common complication of open fractures and antibiotic therapy should be performed in all cases of open fractures (4, 5). The use of systemic antimicrobials has been considered the standard in the treatment of open fractures since 1974 when Patzakis et al. (14) observed that patients treated with cephalothin showed lower rates of osteomyelitis compared to patients treated with penicillin and streptomycin. The ideal time for treatment with antimicrobials is uncertain and most authors

Table 3. Degree of Inflammation of Bone Fragment Through the Score Smeltzer

Value	Bone Histology Mean Punctuation	P Value
CT Group		
Intraosseous acute inflammation	0 ± 0	-
Intraosseous chronic inflammation	1.0 ± 0.6	-

Bone necrosis	0.8 ± 0.4	0.005
Total	6.7 ± 2.2	0.007

recommend its use for up to three days after injury (15). Despite the intravenous use is still considered the standard, the local application of antibiotics seems as an alternative for prophylaxis of bone infections leading to high local concentrations of antibiotics and low systemic levels (16). The choice of the antimicrobial agent to be used is also controversial, with ciprofloxacin been an option in the treatment of open fractures due to its action against Gram-positive and Gram-negative organisms (17).

In the present study, an experimental model of an open fracture was performed to evaluate the effectiveness of prophylaxis of infection in each group tested, verifying the occurrence of osteomyelitis. This model was suggested by Lindsey et al. (12), who proved an index of reproducible osteomyelitis of 90% to 100% after 21 days after the experimental fracture, the same was observed in this research, because five of the six animals in the IC group developed in-

fection after a period of 21 days after surgery. Ciprofloxacin was used for acting appropriately in the prophylaxis of infections secondary to open fractures and was stable when combined with a chitosan film. The antibiotic was used for three days after the injury.

PMMA is the current standard vehicle for local antibiotics delivery in orthopedic surgery (18-21). However, it needs thermostable antibiotics, provides uncontrolled release of drugs and surgical removal is necessary because it is not biodegradable (21). A number of experimental studies have suggested the use of other options for local antibiotic delivery such as a chitosan film impregnated with antimicrobial (16, 21-25).

In this study, chitosan was used as a vehicle, because it has the ability to transport drugs like PMMA, with the additional benefit of possessing antibacterial activity (26) and be biodegradable (8, 16, 21, 25); so, a second surgical pro-

cedure is not required to remove it from the wound. Besides, chitosan does not increase the temperature during the manufacturing process and can be combined with any antibiotic, not requiring drugs that have thermal stability.

Although Aimin et al. (27) describe the reduction of the infection rate of *S. aureus* osteomyelitis in an experimental model using pure chitosan; we did not get the same result. The animals of the C group received pure chitosan films as a treatment for the model of open fracture and presented a high rate of osteomyelitis compared to the CT group that received antibiotic prophylaxis, with a significant difference. Histological evaluation also showed a higher degree of intraosseous chronic inflammation in the C group compared to the CT group, with a significant difference. This result may have been due to the small size of a chitosan film used in our research or extensive soft tissue injury caused by the equipment for inducing fracture that results in more favorable environment to infection.

Orhan et al. (22) evaluated the efficacy of chitosan microspheres and pectin impregnated with ciprofloxacin in a model of local treatment of osteomyelitis and concluded that this type of treatment was higher than the equivalent treatment intramuscular antimicrobial. Stinner et al. (16) evaluated the efficacy of a chitosan sponge impregnated with amikacin or vancomycin in a model of complex musculoskeletal wound and concluded that this treatment was effective in reducing the bacteria concentration within the wound. In this study, different results were obtained. The CA group exposed to the treatment of an open fracture model through a chitosan film impregnated with ciprofloxacin showed a high rate of osteomyelitis compared to the CT group submitted to antibiotic prophylaxis with a significant difference. This result can be justified by the small amount of antibiotic associated to a chitosan film used in this study where the preparation had 10% of the molecular weight of the membrane in antibiotic.

Further studies will be necessary to assess whether the membrane of chitosan impregnated with ciprofloxacin in higher concentrations of antibiotics or larger than that used in this study will be effective in the prophylaxis of osteomyelitis secondary to fractures. There are not studies in the literature using chitosan films impregnated with ciprofloxacin for the prophylaxis of osteomyelitis secondary to open fractures.

As a strong point this study bring a new method of the treatment for open fractures with local delivery of antibiotics through chitosan films resulting in higher local concentrations of drugs and lower systemic concentrations and lower side effects. The weak points of this study is that it is an experimental study, not tested in humans and used just the concentration of 10% of antibiotics in chitosan films that was not effective to avoid infection in this

model of open fracture.

5.1. Conclusion

The chitosan film pure or impregnated with ciprofloxacin showed no efficacy in the prophylaxis of osteomyelitis.

Acknowledgments

The authors would like to thank the Universidade Federal de Minas Gerais for their support in conducting this study.
