Abstract

It has been hypothesized that low frequency (1–5% minor allele frequency (MAF)) and rare (<1% MAF) variants with large effect sizes may contribute to the missing heritability in complex traits. Here, we report an association analysis of lipid traits

(total cholesterol, LDL-cholesterol, HDL-cholesterol triglycerides) in up to 27 312 individuals with a comprehensive set of low frequency coding variants (ExomeChip), combined with conditional analysis in the known lipid loci. No new locus reached genome-wide significance. However, we found a new lead variant in 26 known lipid association regions of which 16 were >1000-fold more significant than the previous sentinel variant and not in close LD (six had MAF <5%). Furthermore, conditional analysis revealed multiple independent signals (ranging from 1 to 5) in a third of the 98 lipid loci tested, including rare variants. Addition of our novel associations resulted in between 1.5- and 2.5-fold increase in the proportion of heritability explained for the different lipid traits. Our findings suggest that rare coding variants contribute to the genetic architecture of lipid traits.

Introduction

Genome-wide association studies (GWAS) have identified hundreds of mainly common variants that are robustly associated with cardiometabolic traits (1–4). For lipid levels, a series of large-scale meta-analyses ($N > 100\ 000$) identified a total of 164 independent single nucleotide polymorphisms (SNPs) in 159 loci contributing to variation in plasma concentrations of total cholesterol (TC), triglycerides (TG), low-density lipoprotein cholesterol (LDL-C) and high-density lipoprotein cholesterol (HDL-C) (2,3,5–8). Blood lipid levels have an estimated heritability of 40–70% (9); however, variants reaching genome-wide significance explain only ~15% of the heritable fraction for these traits (2,3). The clinical relevance of these 164 SNPs of which 71 associate with more than one lipid trait is underscored by an overall excess of significant association signals for coronary artery disease (CAD), fasting glucose, type 2 diabetes, blood pressure traits and body mass index among them (2).

It has been hypothesized that low frequency (1–5% minor allele frequency (MAF)) and rare (<1% MAF) variants with larger effects may account in part for the missing heritability in complex traits (10,11). To test this hypothesis in relation to lipid traits we used the Illumina HumanExome Beadchip (ExomeChip), an array which provides comprehensive coverage of low frequency coding variants (non-synonymous, splice-site and stop altering), to profile 27 312 individuals. The Exome array also includes most of the lead (or a proxy) GWAS variants in the 159 known lipid loci which allowed to assess the independent contribution of additional, mainly low frequency, coding variants in these loci by performing conditional analysis with the GCTA software.

Results

Single-marker analysis

In our single-marker meta-analysis of ExomeChip (Illumina) data in 27 312 individuals (an overview of the study design is given in Fig. 1), we did not find any new variant associated with a lipid trait at either a genome-wide threshold of significance ($P < 5 \times 10^{-8}$) or an array-wide threshold of significance ($P < 2 \times 10^{-7}$) outside the 159 previously reported loci (considering a 1 Mb window centred on the sentinel SNP).

The 159 unique loci known to be associated with one or more lipid traits represent 247 association signals (73 for HDL-C, 58 for LDL-C, 74 for TC and 42 for TG) (3,6–8, 12). The ExomeChip array does not have a good proxy of the reported sentinel SNP (2,3) in 21 of the 159 lipid loci (see Materials and Methods). In our study, we detected 209 association signals with a lipid trait (55 for HDL-C, 50 for LDL-C, 67 for TC and 37 for TG) at $P < 0.01$ (nominal significance; direction of effect same as published (2)) in 135 of the 159 unique lipid loci (Supplementary Material, Table S1). Of the remaining 24 loci, 9 had no lead SNP or a proxy

on the ExomeChip, 4 had the lead SNP or proxy fail QC, and 11 did not show a nominal association in our study.

Further assessing the results of our single-marker analysis, we found that in about half ($n = 98$) of the 209 association signals (26 for HDL-C, 17 for LDL-C, 35 for TC and 20 for TG), the lead SNP was either the published one or a highly linked proxy ($r^2 > 0.8$; Supplementary Material, Table S1); in two instances, the proxy is a putative functional variant (rs2792751 in *GPAM* for LDL-C and rs35332062 in *MLXIPL* for TG) (Supplementary Material, Table S1). In many loci, our top hit was different than the previously published lead SNP (this study) and not in close LD ($r^2 < 0.8$) (Supplementary Material, Table S1). Table 1 lists the 27 most significant of these associations ($P < 10^{-4}$) of which eight are due to low frequency or rare coding variants. Interestingly, for 16 of these 27 association signals, the new

[17]did not reach significance threshold in joint analysis ($P_J > 0.05$; see text).

sentinel variant was >1000-fold more significant than the previously published one. These results were also corroborated with one exception by conditional and joint analyses (see below); SNP rs5015480, a downstream variant in *CYP26A1* previously reported for T2D (13), was not significant in the joint analysis. For the remaining 11 signals, the new sentinel variant was only marginally more significant than the previously published one (includes two low frequency variants in *LPA* and *KDM2B*).

Among the 27 association signals (Table 1), four variants had not been previously associated with a lipid trait. Two of them had a 1000-fold more significant association for TG levels than the previous sentinel SNP: rs72836561 a missense variant in *CD300LG* (p.R82C) and rs3094216 a synonymous variant (p.C448=) in *CDSN*. The other two variants were rs3751813 (TG association) an intronic variant in the *FTO* gene andrs34606562 (TC association) a synonymous change (p.L1174=) in *KDM2B* both of which overlap a strong peak for H3K27Ac which marks active regulatory elements. In the *LPA* locus, the missense variant rs3798220 (p.I1891M) previously associated with Lp(a) lipoprotein levels and CAD (14) had the strongest signal for LDL-C.

In 15 of the 135 lipid loci with an association signal in our data ($P < 0.01$), we lacked the published lead SNP or a proxy (12 not on the ExomeChip and 3 QC failures; Supplementary Material, Table S1, column AJ) and therefore we were unable to undertake a direct comparison of the strength of association between our top hit and the published one. However, in one such locus, *ABCA8*, which is associated with HDL-C (2,3), we found a missense variant (rs77542162; Cys1319Arg; 1.57% MAF) associated with both LDL-C ($P = 6.40 \times 10^{-13}$) and TG ($P = 6.23 \times 10^{-11}$) but not HDL-C ($P = 0.46$) located in the *ATP-binding cassette, subfamily A (ABC1), member 6 (ABCA6)* gene (Supplementary Material, Table S1). *ABCA6* encodes a membrane-associated protein and is located together with *ABCA8* and three other *ABC1* family members on 17q24. *ABCA6* may play a role in macrophage lipid homeostasis (15) and in intercellular lipid transport processes in vascular endothelial cells (16).

Conditional analysis

We next undertook conditional analysis which looks for association signals that are independent of the lead SNP from the unconditional analysis, in the 135 unique loci harbouring 209 lipid association signals at a nominal significance level of $P < 0.01$ (boundaries are listed in Supplementary Material, Table S2) using the GCTA software (17) and meta-analysis summary statistics from all 27 312 samples. We considered a signal from the conditional analysis to be significant if it passed a Bonferroni correction threshold based on the number of SNPs tested across the locus examined (Supplementary Material, Table S2). Therefore only loci which had a lead SNP with $P_{unconditional}$ less than the locus-wide Bonferroni threshold for multiple testing (i.e. based on the number of tested SNPs per locus) were amenable to conditional analysis. Based on the threshold calculated for each locus (Supplementary Material, Table S2), it was possible to examine 98 of the 209 lipid association regions for a secondary signal (see Materials and Methods; Supplementary Material, Table S1). We found 31 (31.6%) of these association regions to have at least one additional independent signal. In total, we identified 89 independent signals (29 for HDL-C, 16 for LDL-C, 19 for TC and 25 for TG) in the 31 association regions (Table 2 and Supplementary Material, Table S3) corresponding to the 31 sentinel SNPs from the unconditional analysis and 58 SNPs from the subsequent rounds of conditional analysis. The largest

number of independent signals per locus was 5, in the *APOA1* locus for HDL-C as well as in the *APOB* and *APOE* loci for LDL-C (the latter illustrated in Supplementary Material, Fig. S1). Approximately 30% of the 89 independent variants were either low frequency (13; 14.6%) or rare variants (14; 15.7%) (Supplementary Material, Table S1).

Out of the 58 additional signals identified from the conditional analysis, 42 have previously been associated with a lipid trait (34 reported for the investigated lipid trait and 8 for a lipid trait other than the investigated one; Supplementary Material, Table S3) and 16 have not been previously associated with any lipid trait (Table 2). Among the 34 lipid signals previously reported, two variants, rs439401 in *APOE* (TC) and rs35120633 in *APOA1* (TG and HDL-C), showed an increase in their effect size after conditioning for the top hit in the corresponding region. In both instances, the very strong association signal of the lead SNP in the region (e.g. rs7412 $P = 7.43 \times 10^{-145}$ in the *APOE* locus) appears to partially mask the weaker secondary signal. In the unconditional analysis, SNP rs439401 had an effect size (β) of -0.051 per T allele ($P = 1.77 \times 10^{-8}$) whereas after conditioning on rs7412 the β doubled to -0.103 ($P = 3.70 \times 10^{-31}$); this variant has been associated with HDL-C and TG as a bivariate phenotype (18). Similarly, the association of rs35120633 with TG and HDL-C (unconditional $P = 2.67 \times 10^{-40}$ and $P = 2.02 \times 10^{-9}$, respectively) became stronger after conditioning on rs2266788 ($P = 5.21 \times 10^{-46}$ and $P = 1.38 \times 10^{-10}$, respectively).

Of the 16 conditional signals not previously associated with a lipid trait, 10 are rare variants (Table 2). These variants are missense except rs76353203 (MAF 0.04%; β = -1.258 per T allele) which introduces a stop codon in *APOC3* (Arg19TER) and is known to cause hyperalphalipoproteinaemia 2. At several loci, conditional analysis identified variants with much larger effect sizes than the sentinel SNP, e.g. missense variant rs116329129 (rs116329129:T > C, p.V280A; MAF 0.03%) in *BANK1* which was associated with HDL-C, had a β of -1.835 per C allele compared with -0.104 for the lead variant rs13107325 (MAF 6.02%) which is located in *SLC39A8*. The B-cell scaffold protein with ankyrin repeats 1 (*BANK1*) gene encodes a B-cell-specific scaffold protein involved in B-cell receptor-induced calcium mobilization from intracellular stores. Variants in *BANK1* have been associated with susceptibility to systemic lupus erythematosus (19). Similarly, the missense variant rs139788907 (MAF 0.03%) in the phospholipase A2, group IVF (*PLA2G4F*) gene (rs139788907:A > G, p.L326P; deleterious change per SIFT) which was associated with TG levels, had a β = 1.665; ~1.98 mmol/l per G allele) 10-fold higher than that of the intronic lead variant rs2412710 (MAF 1.8%; β = 0.165; 0.20 mmol/l per G allele) which is located in *CAPN3*. *PLA2G4F* encodes a calcium-dependent phospholipase A2 that selectively hydrolyzes glycerophospholipids in the sn-2 position.

Joint analysis

Regional analyses can determine the specific contribution that each locus makes to the trait heritability. The iterative rounds of conditional analyses within GCTA described above enabled the identification of independently associated variants at each locus. Joint analyses can simultaneously estimate the effects of each of these significant variants adjusted for all other effects.

The joint analyses were performed in both the discovery studies with appropriate ethical approval for sharing individual level data (16 of the 19 cohorts; N = 24 894) and the replication studies (four cohorts; N = 9029), in order to (i) validate the

Table 2. New variants identified as independent signals in the approximate conditional analysis

[a]Change in the direction of the conditional effect.
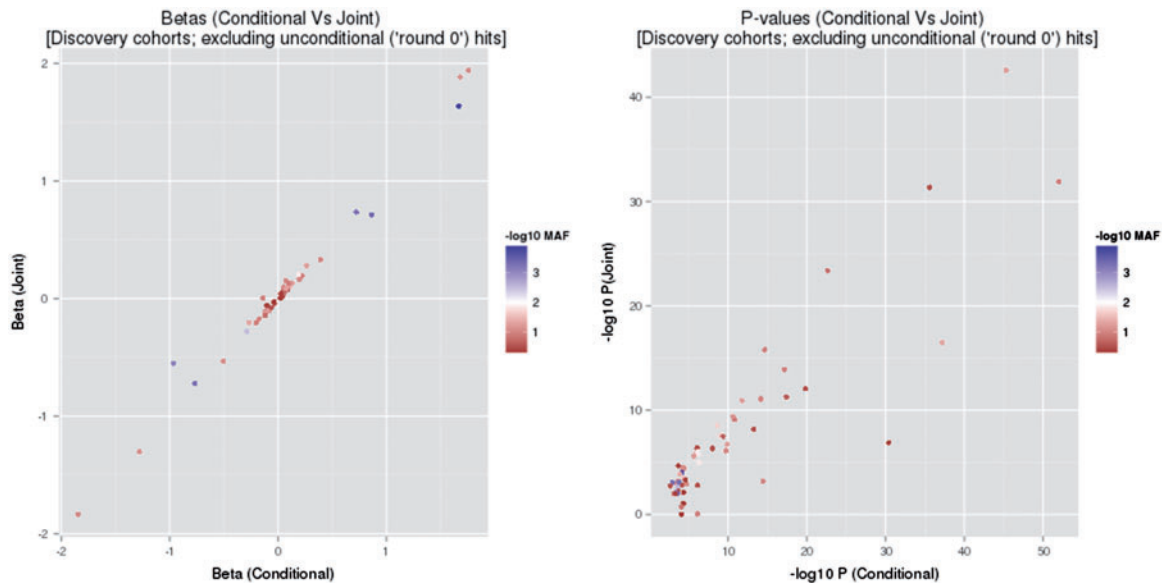

Figure 2. Comparison of results between conditional and joint analyses. Note that these figures do not include the lead SNP in each region (i.e. round > 0 means that variants from the conditional analysis are shown only), as the conditional analyses do not produce adjusted estimates of their effects in contrary to the joint analyses.

original conditional analyses based on GCTA regarding the handling of rare and low-frequency variants as well as check for any impact of sample size difference and (ii) confirm consistency between the discovery and replication studies, to ensure that the replication data are sufficiently concordant to be used for a risk score analyses (see below).

Over 95% of the variants that were significant in the conditional analyses also had $P < 0.05$ in the joint analyses (29/29 for HDL-C; 17/18 for LDL-C; 18/19 for TC; and 18/20 for TG) (Supplementary Material, Table S4). A comparison of the βs between conditional and joint analyses (Fig. 2) revealed close agreement between the two analyses, with almost perfect directional consistency (55 of 56 variants). Comparison of the P-values from each analysis (Fig. 2) also showed close agreement for most variants despite a difference in sample size between the two analyses and the more conservative nature of the joint tests. Importantly, the relationship between P-values did not appear to depend on MAF, and none of the variants with noticeably discordant P-values was rare or of low frequency. Of the four variants with $P > 0.05$ we excluded rs5015480 and rs2068888 (TG signals in *CYP26A1*) from further analyses but retained rs3208856 (*APOE*-LDL) and rs920915 (*LIPC*-TC) given that they are established associations. In summary, we found good concordance between the joint and conditional analyses within the discovery studies.

Joint analysis in the replication studies detected an effect in the same direction for 91.8% of the variants (Supplementary Material, Table S4), showing good concordance between the discovery and replication data sets.

Locus-specific genetic score analysis

Next we calculated an overall genetic risk score association for each region except *CYP26A1* (see joint analysis above), assessing the combined effects of all independent variants within a locus. In such analyses, the score is weighted by the effect sizes of each included variant. We used the beta estimates from the conditional analyses as risk score weights and performed the analyses in the replication set which comprised four

independent studies ($N = 9029$). It is paramount to use an independent data set in order to minimize any bias.

The genetic score analyses identified several strong effects (Table 3; effect estimates are from the unweighted model and are expressed as per one-allele increment); for example, in the *CETP* locus each trait-increasing allele associated with 12.4% of an SD (∼0.06 mmol/l) increase in HDL-C accounting for 3.1% of the overall trait variation. We also note the *PCSK9* locus in which each trait-increasing allele was associated with 19.2% of an SD (∼0.18 mmol/l) increase in LDL-C, but this region accounted for only 0.4% of the variation. *PCSK9* was also associated with a large effect on TC (16.6% of an SD; 0.18 mmol/l per trait-increasing allele), and explained 0.3% of the variation. For TG, the strongest effect was found at the *APOA1* locus (17.2% of an SD; ∼0.20 mmol/l per trait-increasing allele accounting for 1.7% of the variation). Cumulatively per trait, all regions tested accounted for 6.3% (HDL-C), 2.9% (LDL-C), 2% (TC), and 3.8% (TG) of the variation (Table 3).

Heritability

First, we assessed heritability in the 135 unique known lipid loci which reached $P < 0.01$ in our study, considering only the published lead SNP (or proxy) and estimated a 7.12% heritability for HDL-C, 6.52% for LDL-C, 7.03% for TC and 6.31% for TG. When we considered for the same loci all independent sentinel SNPs from our study (lead and secondary signals as per Supplementary Material, Table S1) we observed a between 1.5- and 2.5-fold increase in the heritability estimates (14.73% for HDL-C, 15.06% for LDL-C, 13.49% for TC and 9.62% for TG).

Finally, after exclusion of the *CYP26A1* locus (two variants) we assessed the incremental contribution of the multiple independent signals we detected by conditional analysis in the remaining 30 loci (87 in total) to heritability. Accounting for all signals per locus increased their contribution to heritability estimates for all lipid traits; 4.78% versus 11.07% (HDL-C), 1.26% versus 8.89% (LDL-C), 2.29% versus 7.00% (TC) and 5.70% versus 6.55% (TG) when comparing heritability estimates based on the known sentinel SNPs alone.

Table 3. Association results from the genetic score analyses estimating the combined effect of all statistically significant SNPs within a region by regressing a genetic score against each lipid trait

Discussion

We undertook an association study in 27 312 individuals to test the hypothesis that low-frequency and rare coding variants contribute to the genetic architecture of the four main lipid traits, TC, TG, HDL-C and LDL-C explaining some of the missing heritability in large-scale genetic studies of common variants (2,3). Of the 203 350 non-synonymous (missense, nonsense, splice-site and frameshift) variants present on the ExomeChip, ~64 000 had an MAF above 0.1% to allow for single variant association testing. We did not find any new loci to be significant at the genome-wide level of significance in addition to the 159 loci known to be robustly associated ($P < 5 \times 10^{-8}$) with plasma concentrations of these lipid traits. Our findings are in agreement with other recent studies that have used exome sequencing, exome arrays or 1000 Genome Project imputed GWAS studies to investigate circulating blood lipid levels or related traits (20–22) that have also not found new loci harbouring low frequency/rare coding variants with large effect sizes (21–23).

To extend our assessment of the impact of low frequency/rare coding variation on lipid levels, we also examined the 159 known lipid (2,3) by assessing the results of both the single-marker and conditional analyses at these loci; for the latter, we took advantage of the presence of previously reported index lipid-associated variant (or a good proxy) at 135 of these loci on

the ExomeChip. We note that a recent study by the ENGAGE consortium (24) has identified an additional 10 unique loci associated with lipid traits but the ExomeChip does not harbour the sentinel SNP or a good proxy to allow conditional analysis (seven loci have a variant on the array reaching nominal significance; Supplementary Material, Table S5). Interestingly, in 16 of the loci tested in our study we detected lead variants having an index signal at least 1000-fold more significant than the previously reported sentinel SNP (Table 1); these included variants previously reported in the literature for either the investigated and other lipid traits (10) or lipid traits other than the investigated one (4) as well as two variants not previously associated with a lipid trait (rs3094216 and rs72836561). SNP rs3094216 (MAF 77.6%) is located in the *CDSN* gene, corneodesmosin, which encodes a protein found in human epidermis and other cornified squamous epithelia. Furthermore, rs3094216 is in strong LD with rs3095318 a missense variant in *CDSN* (p. M18L). Mutations in *CDSN* are known to cause peeling skin syndrome type B disease, a rare recessive genodermatosis, whereas a common synonymous SNP (rs1062470) has been associated with psoriasis (25). The other variant, rs72836561, is a low-frequency missense variant in *CD300LG* (p.R82C; MAF 2.69%). *CD300LG* encodes the CD300 molecule-like family member G protein; a type I cell surface glycoprotein that contains a single immunoglobulin V-like domain and has a role in lymphocyte binding and transmigration.

In addition to rs72836561 (*CD300LG*) described above, two more low frequency or rare coding variants had not been previously associated with a lipid trait: the missense variant rs3798220 (p. I1891M) in *LPA* which was associated with LDL-C levels and rs34606562 a synonymous change (p.L1174) in *KDM2B* associated with TC levels. *KDM2B* encodes a member of the F-box protein family which is characterized by an approximately 40 amino acid motif, the F-box. The F-box proteins constitute one of the four subunits of ubiquitin protein ligase complex called SCFs (SKP1-cullin-F-box), which function in phosphorylation-dependent ubiquitination. *KDM2B* gene has been recently associated with methylation in adipose tissue and our lead variant (rs34606562), which overlaps a strong peak for H3K27Ac, is located 95.6 kb away of the methylation probe (cg13708645) used to detect it (26). In total, after taking into consideration the results of the conditional analyses, we found 27 (13 low frequency and 14 rare) variants to be associated with lipid levels. Interestingly, we observed higher effect sizes for variants with MAF below 3% compared with more common SNPs (Supplementary Material, Fig. S2; power calculations based on TC showed 80% power to detect a minimum effect size of 0. 125 at 1% MAF). However, this may reflect the fact that our study only had power to detect rare variants with higher effect sizes.

Overall, our study identified 14 missense variants not previously reported to be associated with a lipid trait. Two of them, rs3798220 and rs72836561, were new sentinel SNPs (Table 1) and the remaining 12 were identified as distinct additional signals through conditional analysis (rs116329129, rs138407155, rs140029729, rs200684324, rs117623631, rs5167, rs36053277, rs145814749, rs1132899, rs5742904, rs139788907, rs5880; Table 2). In total, 21 unique lipid loci (28 regions of association; all lipid traits) where we had the known sentinel SNP on the ExomeChip array had a missense variant as lead SNP ($P < 10^{-4}$) (Supplementary Material, Table S1).

Our joint analyses validated the results from the conditional analyses showing that the GCTA software is also suitable for handling low-frequency variants, despite being designed for common variant analysis. We removed from further analyses

one locus for TG, *CYP26A1*, based on the results of the joint analysis as both variants had $P_j > 0.05$. This was partly due to using a random effect model for rs2068888 which showed significant heterogeneity. In the genetic score analyses, estimating the combined effect of genetic variants within each locus, we observed substantial overall effects on lipid traits in several loci (*CETP*, *PCSK1*, *APOA1*); for example, in the *CETP* locus each trait-increasing allele associated with 12.4% of an SD ($\sim$0.06 mmol/l) increase in HDL-C accounting for 3.1% of the overall trait variation.

As shown by others (24,27–30), we found a substantial increase in the explained variance when we assessed heritability estimates based on the 209 variants (all traits) identified by both the unconditional and conditional analyses compared to the published lead SNPs in the corresponding 135 loci. In some loci, the inclusion of new independent secondary signals contributes only marginally to heritability estimates. For example, in the *APOE* locus, 96.26% of the locus-specific heritability for TC was explained by rs7412 and rs769449 (72.41% and 23.84%, respectively) which capture the *APOE* 2/3/4 alleles. SNP rs7412 was the most significant variant for TC and LDL-C ($P = 7.43 \times 10^{-145}$ and $P = 1.43 \times 10^{-80}$, respectively) in our study whereas rs769449, a proxy of rs429358 (r^2 0.82), was the lead variant for HDL-C ($P = 7.29 \times 10^{-13}$) and a secondary independent signal for TC and LDL-C. For LDL-C, these two variants explain 91.51% of the locus-specific heritability (70.95% and 20.56%, respectively). Among the three additional secondary signals in the *APOE* locus for LDL-C, the low-frequency missense variant rs3208856 explained most of the remaining variance (7.55%). Overall the inclusion of low frequency/rare variants appears to significantly impact heritability estimates, for example, we observed a 7-fold increase in LDL-C variance explained cumulative when comparing only the loci that harboured secondary signals. But rare coding variants with large effect sizes are not likely to explain the overall missing fraction of the genetic component of lipid traits.

Some important limitations of our study merit to be highlighted. First, the list of tested coding variants is by no means exhaustive especially at the rare end of the frequency spectrum. Hamond et al. estimated the Exome array to capture 72.5% and 66.2% of loss-of-function and missense variation with MAF 0.5% and 0.1%, respectively (31). Second, our study does not have sufficiently high power to detect very low-frequency and/or rare variants with small effect sizes. Power calculations for our study (based on TC) showed that we had 80% power to detect a minimum effect size of 0.07 at a 3% MAF, 0.125 at 1% MAF, 0.4 at 0.1% and 1.25 at 0.01% MAF. Therefore, even larger sample sizes will be required to identify new rare variants with small effect sizes.

In conclusion, we demonstrate that low frequency/rare coding variants contribute to the genetic architecture and heritability of lipid traits despite a paucity of low-frequency coding variants with large effect sizes.

Materials and Methods

Samples and phenotypes

We collected summary statistics for ExomeChip SNPs from 19 studies (N $\sim$ 26 000). Among these, 17 studies consisted primarily of individuals of European ancestry, and two studies consisted of individuals of South Asian descent (see Supplementary Material, Note and Table S6 for details). Both population-based studies and case–control studies were included; for case–control studies, cases and control samples were analysed separately. Results for blood lipid levels were provided in mmol/l units and

trait residuals within each cohort were adjusted for age, age[2] and sex, and then inverse-rank normalized. Individuals known to be on lipid-lowering medication were excluded from the analysis (Supplementary Material, Table S6).

Genotyping

A total of 247 870 genetic variants were genotyped using the Illumina ExomeChip array. The ExomeChip variants comprise 203 350 non-synonymous, 10 690 splice and 5641 stop variants as well as 4761 SNPs from the GWAS NHGRI catalogue. Genotypes were called with GenCall, subjected to QC (Supplementary Material, Table S7) to remove poor quality samples and finally recalled using zCall, an algorithm optimized for rare variant detection (32). Average standard errors for association statistics from each study were plotted against study sample size to identify outlier studies. Allele frequencies were inspected to ensure all analyses used the same strand assignment.

Primary linear regression analysis

Analyses were performed for each trait (HDL-C, LDL-C, TC and TG) using the assumption of an additive genetic model. Individual SNP association tests were performed using linear regression with the inverse normal transformed trait values as the dependent variable and the expected allele count for each individual as the independent variable. Explicit adjustments for population sub-structure using principal components (33) were carried out. These analyses were performed using a range of analytical software (Supplementary Material, Table S7).

Meta-analysis

An inverse-variance weighted meta-analysis using a fixed effect model was performed, using both GWAMA (34) and METAL (35) and results were compared and checked for consistency. SNPs were excluded from the meta-analysis if they had MAF >5% and were absent in >90% of the samples or had MAF <5% and absent in >25% of the samples and present in at least two studies and/or failed cluster plot evaluation. Heterogeneity was evaluated using Cochran's Q- and I^2-statistic. For SNPs with non-significant heterogeneity (P for $Q > 0.01$), we report the results from the fixed effect model whereas in the presence of significant heterogeneity (P for $Q < 0.01$) we used a random effect model. Signals were considered to be novel if they reached a genome-wide significance ($P < 5 \times 10^{-8}$) in the meta-analysis and were > ±500 kB away from the nearest previously described lipid locus. For the previously published lipid loci, we considered replication at nominal significance level of $P < 0.01$. We note that for 21 loci the published lead SNP was not present on the ExomeChip and for a further 7 loci it was removed during QC (Supplementary Material, Table S8).

Approximate conditional analysis

Conditional analysis was implemented in GCTA (17) using meta-analysis summary statistics from all 27 312 samples. A subset of 11 396 samples (part of the contributing studies: BC1958, BRIGHT, FIA3, EPIC and GoDARTS) of European origin was used as a reference panel for LD calculations. We considered in total 159 published lipid loci (2,3) and 247 lipid association signals (73 for HDL-C, 58 for LDL-C, 74 for TC and 42 for TG).

SNPs failing the cluster plot inspection were replaced by the next most significant SNP in the locus. Subsequent rounds of stepwise conditional analysis were performed in each locus until no significant SNP could be identified. The level of significance for each round of the conditional analysis was defined as 0.05/(locus SNP content − conditional SNPs) to account for multiple testing (Supplementary Material, Table S2).

Joint analyses

Joint analyses were performed for any loci identified in the conditional analyses as containing more than one statistically significant SNP. The joint tests estimated the associations between the phenotype and all statistically significant independent SNPs within a region simultaneously (by fitting one linear regression model per region).

Locus-specific genetic score analyses

The genetic score analyses estimated the combined effect of all statistically significant SNPs within a region (Supplementary Material, Table S2) by regressing a genetic score against the phenotype. Genetic scores were derived in two ways: (i) by summing the number of trait-increasing alleles (as defined by the estimated directions of the SNP effects in the conditional analyses) carried by each individual; and (ii) by producing a weighted sum of the number of trait-increasing alleles against the phenotype (36). In this latter scenario, the genetic scores were weighted by multiplying genotypes by the corresponding estimated SNP effect (i.e. the 'β') from the conditional analysis. Joint tests and genetic score analyses were performed on the inverse-rank normalized trait values, which had been adjusted for age, age[2] and sex. Adjustments for principal components were also made, where applicable, to control for any potential population stratification within each study.

The joint analyses were run in a total of 20 cohorts ($N_{max} = 33\ 923$). Of these, 16 ($N = 24\ 894$) contributed to the individual SNP meta- and conditional analyses and were considered 'discovery' cohorts, whereas a further four cohorts ($N = 9029$) that did not contribute to the preceding analyses were also included as 'replication' cohorts. The genetic score analyses were only run in the replication cohorts in order to minimize bias, due to using weights estimated from the discovery meta-analyses. Only studies with unrelated individuals were included in these analyses. Studies with any missing data (i.e. where an SNP had been dropped during QC) within a particular region did not contribute to the overall result for that region.

Linear regression tests and genetic score analyses were conducted separately by each study. Meta-analyses were performed using the *metafor* package in R (37). Overall estimates of the proportion of variation explained by each region (R^2) were derived by taking a weighted average over contributing studies (with weights based on sample size).

Heritability

Heritability estimates were calculated using the multifactorial liability threshold model (38). The calculations are performed using the inverse normal transformed traits meta-analysis results, based on a population SD of 1 and under the additive genetic model assumption. All variants included in the heritability calculations per trait were not in LD ($r^2 < 0.3$).
