Abstract

Background—Given the disproportionately high incidence of early-onset breast cancer and aggressive subtypes such as estrogen receptor (ER) negative tumors in African American (AA) women, elucidation of risk factors for early-onset of specific subtypes of breast cancer is needed.

Methods—We evaluated associations of reproductive, anthropometric, and other factors with incidence of invasive breast cancer by age at onset (<45, 45) in 57,708 AA women in the prospective Black Women's Health Study. From 1995 through 2013, we identified 529 invasive breast cancers among women <45 years of age (151 ER–, 219 ER+) and 1,534 among women 45 years (385 ER–, 804 ER+). We used multivariable Cox proportional hazards regression to estimate hazard ratios (HRs) for associations by age and ER status.

Results—Higher parity, older age at first birth, never having breastfed, and abdominal adiposity were associated with increased risk of early-onset ER– breast cancer: HRs were 1.71 for 3 births versus one birth; 2.29 for first birth after age 25 versus <20 years; 0.61 for ever having breastfed versus never; and 1.64 for highest versus lowest tertile of waist-to-hip ratio. These factors were not associated with ER– cancer in older women or with ER+ cancer regardless of age.

Conclusions—Differences in risk factors by ER subtype were observed for breast cancer diagnosed before age 45.

Impact—Etiological heterogeneity by tumor subtype in early-onset breast cancer, in combination with a higher prevalence of the risk factors in AA women, may explain, in part, racial disparities in breast cancer incidence.

Introduction

While overall breast cancer incidence is similar in African American (AA) and U.S. white women, AA women have a 70% higher incidence of the most aggressive subtypes such as estrogen receptor (ER) negative tumors (1, 2), leading to higher mortality (2). In addition,

Disclosure of Potential Conflicts of Interest

relative to white women, AA women are more likely to be diagnosed at younger ages (3, 4). Among women ages 20–49, breast cancer mortality rates in the U.S. are now twice as high in AA women compared to white women (14.3 vs. 7.1 per 100,000) (5), underlining the urgent need to understand etiology and identify modifiable risk factors for breast cancer in young AA women.

It has long been recognized that breast cancer is a heterogeneous disease and that epidemiologic risk factors differ in their associations by hormone receptor subtype (6). More recently, based on observed bimodal age distributions in breast cancer incidence, Anderson et al. proposed that early-onset breast cancer, enriched with ER-negative tumors, and later-onset breast cancer, enriched with ER-positive tumors, are etiologically distinct (7–9). We and others have reported differential patterns of associations of several breast cancer risk factors by ER status overall in AA women (10–15), but whether those differences exist for early-onset breast cancer is unknown. Therefore, we assessed the relation of reproductive, anthropometric, and other factors to risk of breast cancer in young women (age <45), overall and by ER status, within the Black Women's Health Study (BWHS). We conducted similar analyses for women aged 45 and above as a comparison.

Materials and Methods

Study population

The BWHS is an ongoing prospective cohort study of 59,000 AA women (16). In 1995, women ages 21 to 69 years (median age, 38) enrolled in the study by completing a comprehensive self-administered baseline questionnaire. Biennial follow-up questionnaires are mailed to participants to update information on demographic, reproductive, behavioral, and lifestyle factors as well as medication use and medical history. Notices of deaths are obtained from next-of-kin, the U.S. Postal Service, and yearly searches of the National Death Index. Follow-up of the baseline cohort has been successful for 87% of potential person-years.

For this analysis, women were excluded if they had been diagnosed with breast cancer (n=769) or any other type of cancer (except non-melanoma skin cancer) (n=523) before baseline in 1995; the final analytic cohort included 57,708 AA women ages 21–69 at baseline.

The study protocol was approved by the Boston University Institutional Review Board.

Case ascertainment

Incident cases of invasive breast cancer in the BWHS were ascertained through self-report on biennial follow-up questionnaires (95%) or identified through death records and linkage to 24 cancer registries in states covering 95% of participants (5%). Women who reported incident breast cancer were asked for written permission to review their medical records. Study investigators blinded to exposure information reviewed all available medical records and pathology reports, as well as cancer registry data, to confirm breast cancer diagnoses and to abstract data on tumor characteristics. Of cases for which pathology records have been received to date (>80%), more than 99% were confirmed.

Through 2013, we identified 529 incident cases of "early-onset" invasive breast cancer, defined for the purposes of this research as diagnosis before age 45. Of these, 151 cases were classified as ER– and 219 as ER+. Among women ages 45 years, there were 1,534 incident invasive breast cancers with 385 classified as ER– and 804 as ER+. The distribution of ER status was similar to that reported elsewhere for African American women (17–19). In addition, the distribution of breast cancer risk factors was similar in cases with known and unknown receptor status (20, 21).

Risk factor assessment

The baseline questionnaire collected information on established and putative risk factors for breast cancer including adult height, current weight, waist and hip circumferences, age at menarche, weight at age 18, oral contraceptive use, number and timing of births, duration of lactation, hysterectomy, breast cancer in first-degree relatives, alcohol consumption, cigarette smoking, physical activity, menopausal status, age at menopause, and use of menopausal female hormone supplements. Except for adult height, age at menarche, and weight at age 18, all information was updated on follow-up questionnaires. Self-reports of weight, height, waist circumference, hip circumference, and vigorous physical activity were significantly correlated with objective measures in a validation study (22). Body mass index (BMI) was calculated as weight in kilograms divided by the square of height in meters. We did not assess associations of menopausal status, age at menopause or use of female hormone supplements as risk factors in this report because the vast majority of women <45 years of age were premenopausal and had never used hormone supplements.

Statistical analyses

We used the Andersen-Gill data structure (23), with one record per woman per 2-year questionnaire cycle, to allow for time-varying risk factors and survival analysis with time at risk as the underlying timescale. Women contributed person-years from the beginning of follow-up in March, 1995 until diagnosis of breast cancer, death, loss to follow-up, or end of follow-up in March, 2013, whichever occurred first, for a total of 881,204 person years. We used multivariable Cox proportional hazards regression models, stratified by age in one-year intervals and questionnaire cycle, to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for risk of overall, ER-, and ER+ breast cancer, separately, in relation to each factor listed above. All analyses were stratified by age (<45 and 45) to compare associations for early- vs. later-onset breast cancer and all models were mutually adjusted for all risk factors as well as smoking history, menopausal status and, for older women, age at menopause and duration of combination (estrogen plus progestin) menopausal hormone supplement use. HRs for age at first birth, time since last birth, and lactation were estimated from models fit among parous women only. Time-varying risk factors were updated at each questionnaire cycle. Missing indicator categories were used to account for missing information in risk factors (generally 2–4%). To test whether the risk factor associations differed by ER status within each age group, we used the contrast test method for heterogeneity by subtype (24). Finally, we evaluated statistical interaction of risk factors with age using a likelihood ratio test, comparing main-effects only models with models including cross-product terms for age (<45 vs. 45) and each categorical risk factor. All analyses were performed using SAS 9.4 (Cary, North Carolina).

Results

Compared with breast cancers diagnosed at age 45 and older, cancers that occurred in women under age 45 were more likely to be ER– (41% vs. 32%) and to have other aggressive tumor features, such as advanced stage of disease (regional or distant, 50% vs. 35%), higher grade (poorly differentiated or undifferentiated, 57% vs. 46%), and larger tumor size (>2 cm, 47% vs. 34%) (Table 1). Characteristics of the study population according to age group are available in the Supplementary Table. Other characteristics of the overall study population at baseline have been presented elsewhere (25, 26).

Associations of known and suspected breast cancer risk factors with incidence of breast cancer before age 45, overall and by ER subtype, are shown in Table 2. Family history of breast cancer, early age at menarche, recent oral contraceptive use, and pregnancy within the previous 10 years were associated with increased risk of both subtypes, and higher BMI at age 18 was associated with reduced risk of both subtypes. Other associations differed by ER subtype: breastfeeding was associated with a reduced risk of ER– breast cancer [HR (95% CI): 0.61 (0.40, 0.92)] but was not associated with ER+ breast cancer; high parity was associated with increased risk of ER– cancer [1.71 (0.98, 2.99)] but with a reduced risk of ER+ cancer [0.69 (0.41, 1.14)]; and late age at first birth was associated with increased risk of ER– cancer [2.29 (1.32, 3.97)] but not ER+ cancer (p-heterogeneity <0.05 for each of the three factors). There was also significant heterogeneity in the results for waist-to-hip ratio, with a 64% increased risk of ER– breast cancer for women in the top relative to the bottom tertile (95% CI: 1.04, 2.59) and no apparent increase in risk of ER+ breast cancer.

Results from analyses of women 45 years of age are shown in Table 3. BMI 25 kg/m² at age 18 was associated with decreased risk, while family history of breast cancer, early age at menarche, and recent oral contraceptive use were associated with increased risk of both ER– and ER+ breast cancer. HRs for nulliparity relative to one birth were 0.71 (0.48, 1.07) for ER– breast cancer and 1.17 (0.90, 1.52) for ER+ cancer (p-heterogeneity = 0.05). The other factors examined were not associated with breast cancer risk in women over 45, regardless of ER subtype. In fact, the lack of association for high waist-to-hip ratio with risk of ER– breast cancer in women age 45 and older was in contrast to the strong positive association observed among younger women (p-interaction =0.03).

As noted, having a first degree family history of breast cancer was associated with increased risk of breast cancer in both age groups and for both ER subtypes; however, the positive association was significantly stronger in the younger women (p-interaction =0.02).

Discussion

In this large prospective cohort study of African American women, we identified breast cancer risk factor profiles that differed by age at diagnosis and ER status. Higher parity, older age at first birth, never having breastfed, and greater abdominal adiposity were important risk factors for early-onset ER– breast cancer. These factors were not associated with increased risk of later-onset ER– breast cancer or with ER+ cancers in either age group. Other factors were associated with both ER– and ER+ breast cancer, regardless of age.

In a recent case-control study in Seattle-Puget Sound with approximately 1,000 breast cancer cases diagnosed before age 45, Li et al. reported that parity was associated with reductions in risk of both ER+ and "triple-negative" tumors and that increasing number of live births was similarly associated with reduced risk of both subtypes (27). Non-Hispanic white women comprised approximately 80% of that study population. In contrast, in an analysis of reproductive factors and premenopausal breast cancer diagnosed before age 40 in the predominantly white Nurses' Health Studies (NHS), Warner et al. found a nonsignificant inverse association of parity with ER+/PR+ breast cancer (n=118) but a suggestive positive association with ER - /PR - breast cancer (n=71) (28). In the present study of AA women diagnosed before age 45, we found that higher parity was associated with increased risk of ER- breast cancers. The present analysis updates our earlier reports of parity and lactation in relation to breast cancer in the BWHS (20, 29), and is also consistent with findings of a recent large pooled analysis of AA women, which included the BWHS, in which parity relative to nulliparity was associated with increased risk of ER- breast cancer with risk increasing with number of births (12). While increased risks for parous versus nulliparous were observed across age strata, the association appeared stronger for earlyonset ER- disease, consistent with the current findings. Breastfeeding was associated with reduced risk of early-onset ER- breast cancer in the present study, consistent with our earlier reports (20, 29) with findings from the NHS (28) and with the Seattle-Puget Sound study (27).

Older age at first birth has been fairly consistently positively associated with ER+ breast cancer (30–34), and this association has been observed among both younger and older women (28, 31–33, 35, 36). While we observed a weak positive association for later-onset ER+ breast cancer, we found no apparent association between age at first birth and risk of early-onset ER+ breast cancer. For overall ER– breast cancer, most previous studies have shown no clear association with age at first birth (31, 32), while results from studies in young women have been mixed, with reports of positive (28, 37), inverse (27, 36), and null associations (35, 38). In the current analysis, we found that later age at first birth was associated with more than twice the risk of early-onset ER– breast cancer, but not later-onset ER– cancer. These findings suggest that non-hormonal mechanisms of carcinogenesis may contribute to the associations with ER-breast cancer, which may be particularly relevant for younger women.

We also observed a positive association of waist-to-hip ratio with early-onset ER– breast cancer. The existing literature on central adiposity and breast cancer risk, is not consistent (17, 39–47). In the Nurses' Health Study II, Harris et al. reported a significant 2-fold increased risk of ER– breast cancer (n=131) for women in the highest quintile of waist-to-hip ratio compared to the lowest, after adjustment for BMI (40); similar positive associations with ER– disease were observed in a U.S. case-control study (48) and a Finnish case-control study (49). Other studies in premenopausal white or multiethnic populations, however, found no associations (37, 43, 50). Current findings from the BWHS are consistent with results from the Carolina Breast Cancer Study (CBCS) (17) and the Women's Circle of Health Study (WCHS) (41), both of which reported increased risk of premenopausal ER– breast cancer in AA women associated with measures of central adiposity (e.g., waist circumference and waist-to-hip ratio).

There is consistent evidence that higher BMI in young adulthood is associated with decreased risk of both pre- and postmenopausal breast cancer (51–60), although few studies have examined this association by age at onset (52, 61–63) or ER status (57, 58, 63). In the present study, we found strong inverse associations of BMI at age 18 with both ER– and ER + breast cancer diagnosed before age 45. These findings are consistent with results from other studies of younger women that evaluated overall breast cancer (52, 61, 62), In the Seattle-Puget Sound study, there was a non-significant inverse association of BMI at age 18 with risk of triple-negative breast cancer (OR: 0.7; 95% CI: 0.4, 1.2) but no association with ER+ breast cancer (63). While the mechanisms underlying the association between BMI in young adulthood and breast cancer risk are not well understood, proposed hypotheses include less cumulative exposure to endogenous estrogens due to anovulatory cycles in overweight women (64), faster clearance of free estradiol by the liver in overweight women (65), or greater susceptibility to carcinogenic influences in lean women.

Some limitations of this study are worth noting. First, while we were interested in identifying risk factors for early-onset ER– and ER+ breast cancer in AA women, and comparing them to factors associated with breast cancer in older women, we may have been underpowered to detect significant interactions by age. Second, while we had nearly complete data for most risk factors of interest (generally ~2% missing data), there was a fair amount of missing data for waist-to-hip ratio (16%), which required participants to have a tape measure on hand. Third, we did not have information on ER status for 24% of cases; however, the risk factor distribution was similar in cases with and without known ER status, suggesting that any potential selection bias is likely small. We were not able to evaluate associations with triple-negative breast cancer due to small numbers, once we stratified by age.

Despite some limitations, the strengths of this study are considerable, including the prospective design, the large sample size with high follow-up, and high accuracy of reporting of breast cancer diagnoses and risk factor information. Because of the availability of detailed questionnaire data, we were able to perform multivariable analyses including established and suspected risk factors for breast cancer to account for potential confounding. Most importantly, there are very few studies of breast cancer in AA women and even fewer that are able to evaluate risk factors in younger AA women. We have reported on many of the risk factors evaluated in prior analyses (20, 21, 56, 66–68). Now, with the accrual of sufficient numbers of breast cancer cases in the BWHS, the current analysis represents the first study to prospectively characterize risk factor profiles for early-onset ER– and ER+ breast cancer in AA women.

Differential associations of risk factors by age for ER– and ER+ breast cancers in AA women suggest etiological heterogeneity by tumor subtype and are supportive of the hypotheses by Anderson et al. of age-specific subtypes (7–9). Higher parity, never having breastfed, and abdominal adiposity were associated with increased risk of early-onset ER– breast cancer but not with later onset ER– or with ER+ cancer regardless of age. The distribution of these risk factors differs appreciably between AA and white women: AA women tend to have higher parity (69, 70), lower rates of breastfeeding (71–73), and greater abdominal adiposity (74). Therefore, these differences could explain, in part, disparities in

breast cancer incidence between AA and white women, especially for younger women. Some of the identified risk factors, including lactation and higher waist-to-hip ratio, are potentially modifiable, suggesting opportunities for prevention.

Table 1

Breast cancer tumor characteristics by age.

	_			
	Age <4	5 (n=529)	Age 45	5 (n=1,534)
	n	%	n	%
ER status				
Positive	219	59.2%	804	67.6%
Negative	151	40.8%	385	32.4%
SEER stage				
Localized	225	49.7%	832	64.6%
Regional	211	46.6%	401	31.1%
Distant	17	3.8%	55	4.3%
Grade				
Well-differentiated	36	8.5%	187	15.2%
Moderately differentiated	146	34.4%	473	38.4%
Poorly or undifferentiated	243	57.2%	571	46.4%
Tumor size				
1.0 cm	81	19.8%	339	27.7%
>1-2.0 cm	135	32.9%	474	38.7%
>2 cm	194	47.3%	411	33.6%

ER status was unknown or missing for 159 cases <45 years and 345 cases 45 years; SEER stage was unknown or missing for 76 cases <45 years and 246 cases 45 years; grade was unknown or missing for 104 cases <45 years and 303 cases 45 years; tumor size was missing for 119 cases <45 years and 310 cases 45 years.

(premenopausal, hysterectomy only, postmenopausal age <40, postmenopausal age 40–44, postmenopausal age 45, postmenopausal age unknown or missing), postmenopausal hysterectomy only. Multivariable hazards ratios (HRs) adjusted for age, smoking history (never active or passive, passive only, never active/unknown passive, 1-<10 packyears, 10+ packyears), menopausal status years duration, E+P 5+ years duration, other type), and all factors in Table 3.

adjusted for age, smoking history, menopausal status, and all factors in Table 3 except age at first birth; estimates for lactation adjusted for age, smoking history, menopausal status, and all factors in Table 3. ^aAmong parous women only. Estimates for age at first birth adjusted for age, smoking history, menopausal status, and all factors in Table 3 except years since last birth; estimates for years since last birth
