Primary myelofibrosis (PMF) is a clonal hematologic malignancy characterized by BM fibrosis, extramedullary hematopoiesis, circulating CD34⁺ cells, splenomegaly, and a propensity to evolve to acute myeloid leukemia. Moreover, the spleen and BM of patients harbor atypical, clustered megakaryocytes, which contribute to the disease by secreting profibrotic cytokines. Here, we have revealed that megakaryocytes in PMF show impaired maturation that is associated with reduced GATA1 protein. In investigating the cause of GATA1 downregulation, our gene-expression study revealed the presence of the *RPS14*-deficient gene signature, which is associated with defective ribosomal protein function and linked to the erythroid lineage in 5q deletion myelodysplastic syndrome. Surprisingly, reduced GATA1 expression and impaired differentiation were limited to megakaryocytes, consistent with a proproliferative effect of a GATA1 deficiency on this lineage. Importantly, expression of *GATA1* effectively rescued maturation of PMF megakaryocytes. Together, these results suggest that ribosomal deficiency contributes to impaired megakaryopoiesis in myeloproliferative neoplasms.

Introduction

A hallmark of primary myelofibrosis (PMF) is the presence of increased numbers of clustered, atypical megakaryocytes with hypobulbated, bulbous nuclei and an abnormal nuclear/cytoplasmic ratio (1). These abnormalities are recapitulated in vitro; previous studies have demonstrated that PMF progenitors in culture give rise to increased numbers of megakaryocytes, which display delayed apoptosis, altered proplatelet production, and secretion of increased levels of TGF- β and matrix metalloproteinase 9 (MMP-9) (2, 3). Several lines of evidence suggest that aberrant megakaryocytes directly contribute to PMF. First, megakaryocytes lie in close proximity to hematopoietic stem cells and influence their cell cycle through secretion of TGF- β and CXCL4 (4, 5). Second, elevated levels of megakaryocytes promote BM fibrosis in vivo (6, 7). Third, small molecules that induce maturation of malignant megakaryocytes show strong antitumor activity in myeloproliferative neoplasm (MPN) models (8). Here, we report a detailed analysis of the megakaryocyte lineage in PMF and reveal that impaired production of the transcription factor GATA1, downstream of a ribosomal defect, is the key event that leads to impaired megakaryocyte maturation.

Results and Discussion

We first cultured primary human CD34⁺ cells from the peripheral blood of PMF patients and healthy donors in the presence of 10 ng/ml thrombopoietin (THPO) to induce megakaryocytic differentiation. As previously reported (2, 3), we observed that PMF cultures expanded to a much greater extent than those of healthy individuals (Supplemental Figure 1A; supplemental material available online with this article; <https://doi.org/10.1172/JCI82905DS1>). After 9 days in culture, we observed an 11-fold expansion of PMF cells as compared with a 3-fold expansion of healthy cells. Furthermore, CFU assays revealed that PMF progenitors exhibited a higher capacity to form colonies than healthy cells (Supplemental Figure 1B). We obtained 3 to 4 times as many myeloid and erythroid colonies from the PMF CD34⁺ cells as compared with the healthy controls. The number of megakaryocyte colonies was also increased (Supplemental Figure 1C). We further observed significant reductions in the percentage of the mature CD41⁺CD42⁺ population accompanied by a strong diminution of the ploidy level (Supplemental Figure 1D). On average, a 6-fold reduction in the CD41⁺CD42⁺ population and an 8-fold decrease in cells with a DNA content of 8 N or more were seen. Cytospins confirmed an abnormal morphology of the PMF megakaryocytes (Supplemental Figure 2).

Given the essential role for GATA1 in megakaryopoiesis, we assayed its expression in human patients and mouse models of PMF. In agreement with a previous report (9), we observed that the majority of megakaryocytes in the BM of a PMF patient did

Figure 1. GATA1 protein expression is dysregulated in PMF and the mouse models of the MPNs. (A) Immunohistochemistry for GATA1 in sections of healthy BM and of BM from PMF patients with the *JAK2V617F* mutation. (B) Immunohistochemistry for GATA1 in sections of BM from mice transplanted with WT BM or with cells expressing the *CALR* type 1 mutant. (C and D) Immunohistochemistry for GATA1 in spleen sections from *Jak2V617F Vav-Cre* mice (C) or control littermates or spleens from mice transplanted with WT BM or with cells expressing *MPLW515L* (D). Red arrows, megakaryocytes that do not stain for GATA1; black arrows, megakaryocytes that express GATA1. Note the abnormal morphology of GATA1-deficient megakaryocytes in all models. Original magnification, $\times 500$ (A); $\times 200$ (B–D).

not stain for GATA1 (Figure 1A). These GATA1-deficient megakaryocytes displayed the irregular morphology characteristic of PMF. We confirmed this downregulation of GATA1 in PMF patient megakaryocytes by Western blot (Supplemental Figure 3). Next, we performed immunohistochemistry on spleen and BM sections of mice that expressed calreticulin (*CALR*) type 1 mutant, either a V617F mutation in murine *Jak2* (referred to hereafter as *Jak2V617F*) or a W515L mutation in human *MPL* (referred to hereafter as *MPLW515L*). In all cases, a preponderance of megakaryocytes did not stain for GATA1, and these cells exhibited an abnormal morphology (Figure 1, B–D). A similar reduction in GATA1 protein and morphologic abnormalities was observed in megakaryocytes from THPO-treated mice (10).

We then sorted $CD41^+CD42^+$ cells derived from PMF patients and healthy donors (4 controls and PMF8-16, Supplemental Table 1), prepared mRNA, and performed a genome-wide gene-expression study. Analysis of the data revealed many changes in the PMF cells (Figure 2A). Most notably, several myeloid genes, whose expression is normally lost in mature megakaryocytes, were upregulated in comparison with controls. These included the enhancer binding protein *CEBPA* and growth factor independent 1 (*GFI1*). Consistent with a regulatory circuit among *GATA2*, *GFI1*, and *GFI1B*, we also observed decreased expression of *GATA2* and *GFI1B* (11). Of note, reducing *CEBPA* levels in PMF cells did not rescue the phenotype, while increased

expression of *GFI1* in healthy $CD34^+$ cells did not recapitulate the defects seen in PMF (Supplemental Figures 4 and 5). Genes that were downregulated included several that are associated with megakaryocyte maturation, such as platelet factor 4 (*PF4*) (12). Interestingly, as previously reported (9), we observed that *GATA1* mRNA was modestly elevated or unchanged relative to control megakaryocytes (Figure 2A). This result indicates that the loss of GATA1 protein is a posttranscriptional event.

Next, by Gene Set Enrichment Analysis (GSEA) (<http://software.broadinstitute.org/gsea/index.jsp>), we identified several pathways that were altered in PMF megakaryocytes. These included hematopoietic cell lineage, AKT signaling, and MAP kinase pathways, the latter of which has already been reported (13) (Supplemental Figure 6A). To our surprise, one of the top scoring pathways was the ribosomal protein S14 (*RPS14_DN.V1_UP*) gene signature, which mimics 5q deletion myelodysplastic syndrome (MDS) (14) (Figure 2B). *RPS14* is a component of the 40S ribosomal subunit, and knockdown of this gene impairs 40S ribosomal subunit formation (14). Of note, apart from the prominent erythroid defects, 5q deletion syndrome is characterized by the presence of abnormal hypolobulated megakaryocytes (15). In addition to the *RPS14* gene signature, GSEA analysis revealed that 3 other ribosome-related pathways were suppressed in the PMF megakaryocytes. These include rRNA processing, ribosome biogenesis and assembly, and rRNA metabolic process (Supplemental Figure 6B).

Figure 2. RPS14 is required for megakaryocyte maturation. (A) Fold change in expression of myeloid genes in megakaryocytes derived from PMF specimens or healthy control CD34⁺ cells. Results were derived from the gene-expression arrays. (B) GSEA analysis revealed that the RPS14_DN.V1_UP pathway (RPS14 gene signature) is significantly enriched. NES, normalized enrichment score; FDR, false discovery rate. (C) CD34⁺ cells were transduced with a control lentivirus or a lentivirus encoding either shRPS14 G5 or shRPS14 G8 and cultured under megakaryocytic differentiation conditions including 10 ng/ml THPO. Two representative experiments of 3 are shown. Megakaryocyte differentiation was reduced by 47% ± 24% in the presence of shRPS14. $n = 3$. $P = 0.03$, Student's t test. (D) Protein synthesis assay comparing PMF megakaryocytes with controls. Top panel: flow cytometry analysis of OP-PURO fluorescence in control versus PMF 28 CD42⁺ megakaryocytes. Bottom panel: mean OP-Puro fluorescence intensity for controls versus PMF samples.

Ribosome dysfunction is known to be associated with activation of the p53 pathway (16). The analysis of our microarray data revealed that the p53 pathway was indeed activated in PMF megakaryocytes (Supplemental Figure 7A). To confirm this signature, we performed quantitative reverse-transcriptase PCR (qRT-PCR) on control and PMF samples for 3 genes in the pathway: *TP53*, *CDKN1A*, and *BAX*. The results show increased expression of 2 p53 targets in the PMF cells, confirming the activation of the pathway (Supplemental Figure 7B). We next knocked down *RPS14* in the human *JAK2V617F* mutant (*JAK2V617F*) SET2 megakaryocytic cell line and observed a nearly 4-fold reduction of *RPS14* expression, which was accompanied by an elevated expression of *TP53*, *P21*, and *BAX* (Supplemental Figure 7C).

To investigate whether the ribosomal gene changes and the reduction in *GATA1* expression are restricted to megakaryocytes, we assayed the expression levels of a set of ribosome-associated genes in mononuclear cells and erythroid cells derived from PMF CD34⁺ cells. We did not observe significant changes in these genes in these 2 other lineages, suggesting that the ribosome deficiency is limited to megakaryocytes (Supplemental Figure 8). Similarly, we observed a reduction in ribosome-associated gene expression in megakaryocytes, but not erythroid cells, derived from CD34⁺ cells of polycythemia vera (PV) patients (Supplemental Figure 9 and

Supplemental Table 2). Moreover, differentiation of PV CD34⁺ cells revealed a striking impairment of megakaryopoiesis as assessed by CD41/CD42 staining and ploidy analysis (Supplemental Figure 10). This deficiency is consistent with the known abnormalities in the megakaryocyte lineage in PV; in this disease, megakaryocytes tend to form loose clusters, tend to be located close to bony trabeculae, and show marked pleomorphism with a mixture of different sizes. In addition, megakaryocytes with bulbous nuclei and hypercondensed chromatin can also be present, particularly with increasing BM fibrosis. We also note that there are morphologic abnormalities in megakaryocytes that fail to stain for *GATA1* in mice with the *Jak2V617F* mutation (Figure 1C). Together, our data support a model in which enhanced JAK/STAT signaling leads to a selective impairment of the ribosome in megakaryocytes.

We next transduced human CD34⁺ cells with shRNAs targeting *RPS14* (shRPS14G5 and shRPS14G8) or a control hairpin and then cultivated the cells under megakaryocyte differentiation conditions. Knockdown of *RPS14* was confirmed by RT-PCR (Supplemental Figure 11). With knockdown, we observed a 1.5-fold reduction in the CD41⁺CD42⁺ population in cells transduced by shRPS14G5 and shRPS14G8 in comparison with control, although there was no change in the ploidy state of the cells (Figure 2C and

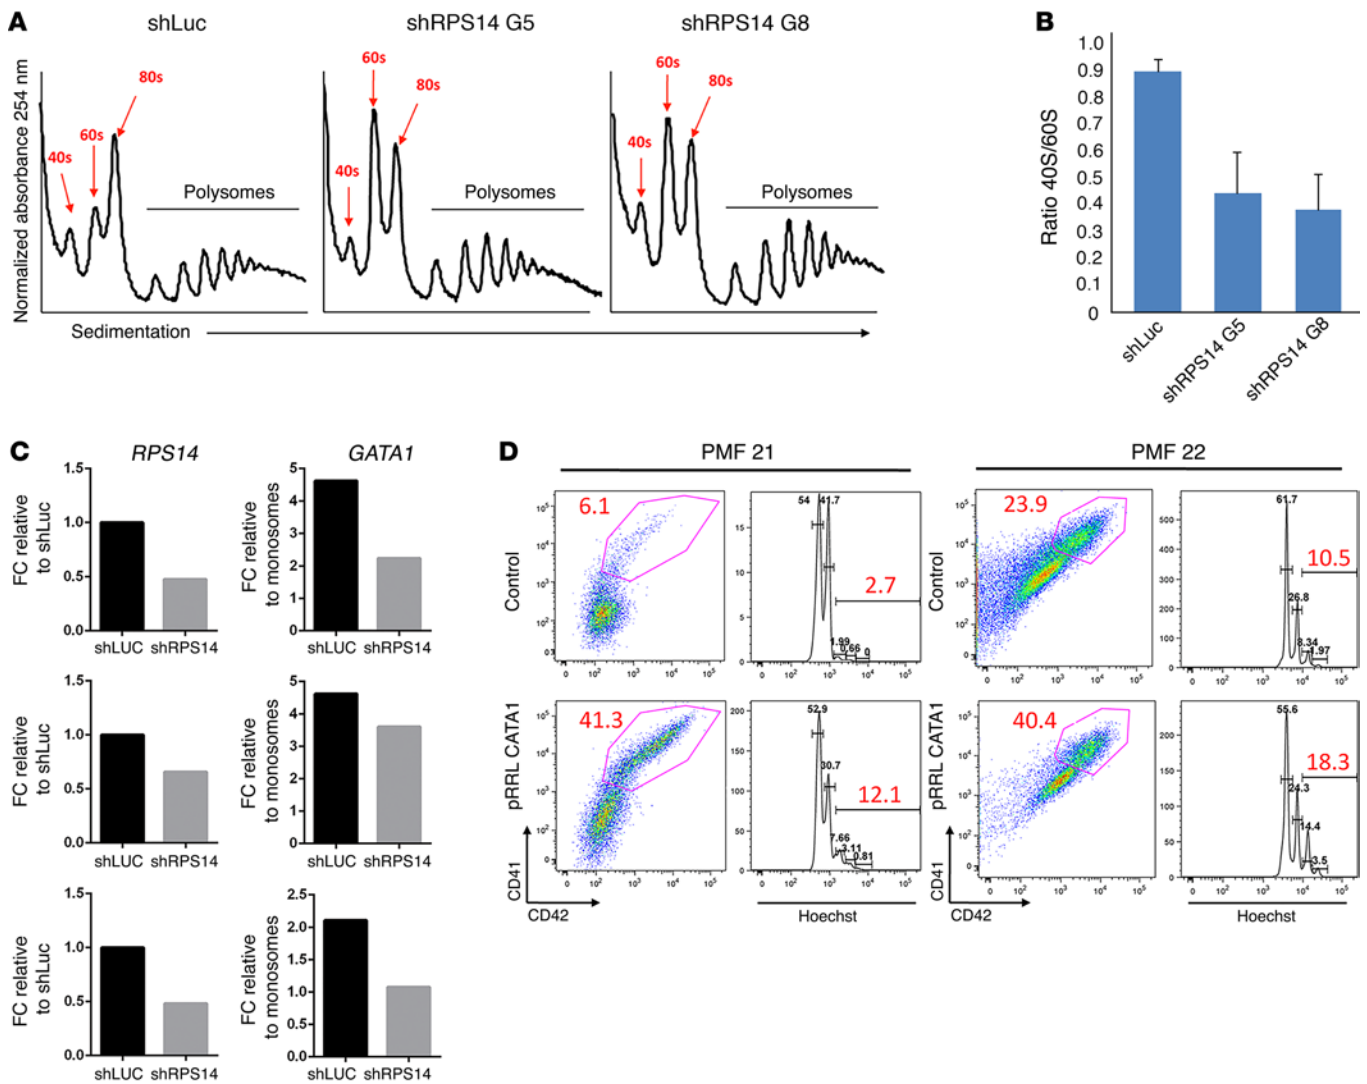

Figure 3. Restoration of GATA1 rescues the differentiation of PMF megakaryocytes. (A) Sucrose gradient polysome profiling showed a reduction in the 40S peak in SET2 cells overexpressing shRPS14 G5 or shRPS14 G8. The 40S, 60S, 80S, and ribosomal complexes are labeled. (B) Histogram showing the reduction in the ratio of 40S:60S subunits in the presence of 2 RPS14 shRNAs. Bar graph depicts mean \pm SD of 2 biological replicates. (C) qRT-PCR showing the fold change in *RPS14* expression upon knockdown (left) and *GATA1* mRNA abundance in polysomes compared with monosomes (right). Data were normalized to *GAPDH*. Three biological replicates are shown. (D) *GATA1* was overexpressed in CD34⁺ from PMF patients (PMF 21 and PMF 22). The numbers in red refer to the percentages of CD41⁺CD42⁺ cells or the percentages of cells with DNA content of 8 N or more. Two representative experiments of 3 are shown. FC, fold change.

data not shown). This result reveals that a ribosome defect leads to aberrant megakaryopoiesis. To provide further evidence for a ribosome deficiency, we compared protein synthesis in megakaryocytes derived from PMF patients or healthy controls. We found that there was a significant reduction in protein synthesis in the PMF cells, consistent with a prominent ribosomal deficiency (Figure 2D and Supplemental Figure 12).

Together, our results are reminiscent of the recent discovery that ribosomal gene mutations in Diamond-Blackfan anemia (DBA) lead to reduced *GATA1* translation (17, 18). Indeed, we observed that knockdown of *RPS14* in SET2 cells led to a reduction in *GATA1* protein (Supplemental Figure 13A). As expected, *RPS14* mRNA was efficiently decreased, but in contrast, *GATA1* mRNA was modestly elevated (Supplemental Figure 13B). This observation confirms that the *RPS14* deficiency acts at the protein, but not

mRNA, level. We also discovered an increase in the levels of genes that are normally suppressed by *GATA1*, such as *CEPBA*, *MYC*, *MYB*, *SPII*, and *IKZF1* (Supplemental Figure 13C).

To investigate how *GATA1* expression is affected by impaired ribosomes, we performed polysome profiling in SET2 cells after *RPS14* knockdown. We saw that the *RPS14* knockdown led to a reduction of the 40S peak as well as the ratio of the 40S/60S subunits (Figure 3, A and B). We then performed RT-PCR to quantify the abundance of *GATA1* mRNA in actively translating ribosomes and observed a 1.3- to 2-fold reduction in *GATA1* mRNA abundance in the polysomes of cells knocked down for *RPS14* (Figure 3C). Since SET2 cells already have a *JAK2* mutation and would be expected to have reduced *GATA1* levels without *RPS14* knockdown, we examined the effect of *MPLW515L* expression on *GATA1* expression in a different megakaryocytic cell line, 6133 (19). We found that 6133

cells with stable *MPLW515L* expression expressed significantly less *GATA1* than the parental cells (Supplemental Figure 14). This result indicates that activation of *JAK/STAT* signaling is sufficient to lead to downregulation of *GATA1* in megakaryocytes.

Finally, we created a lentiviral vector containing the human *GATA1* cDNA and GFP and confirmed expression in transduced cells by RT-PCR (Supplemental Figure 15). Overexpression of *GATA1* robustly improved differentiation of *CD34⁺* cells from PMF patients (Figure 3D). The percentage of *CD41⁺CD42⁺* cells increased on average 3.5-fold upon *GATA1* overexpression relative to GFP alone. Moreover, the percentage of cells with a ploidy of 8 N or more was increased 2.5-fold. As expected, we also observed restoration of *GATA1* target gene expression (Supplemental Figure 16). Together, these data demonstrate that, although there are likely a number of proteins whose expression is reduced by the ribosome defect, the decline in *GATA1* is a critical driver of the phenotype.

Although lenalidomide has had a significant impact on the clinical course in MDS with 5q deletion (20, 21), only modest results have been reported in PMF (22). As an alternative, compounds that induce megakaryocyte polyploidization of even *GATA1*-deficient cells (8) may provide therapeutic benefit by reducing the burden of abnormal megakaryocytes in patients with the MPNs. We note there are 2 limitations to the study. First, the mechanism by which MPN driver mutations cause a ribosomal defect in megakaryocytes is unclear. Second, the way in which a ribosomal defect in these cells leads to downregulation of translation of specific transcripts, such as *GATA1*, also requires further investigation. Nevertheless, our data reveal that the MPNs can be added to the list of hematopoietic diseases that are associated with ribosomal defects, including DBA, 5q deletion syndrome, and Shwachman-Diamond anemia (23).

Methods

Detailed protocols are provided in Supplemental Methods. All original microarray data were deposited in the NCBI's Gene Expression Omnibus (GEO GSE84638).

Statistics. Data are shown as mean \pm SD. *P* values were calculated using Student's *t* test (2 tailed). *P* \leq 0.05 was considered to be significant.

Study approval. Peripheral blood was collected from patients who gave informed consent with approval of the Institutional Review Boards at the Mayo Clinic and Northwestern University. Animal studies were approved by the Northwestern University Institutional Animal Care and Use Committee.

Author contributions

LG, CM, ADA, QJW, PA, MM, QY, KK, and SS performed the experiments, analyzed the data, and contributed to writing the manuscript.
