Abstract

Introduction: The number of children diagnosed with autism spectrum disorder (ASD) has been rapidly rising in the past decade. The etiology of this disorder, however, is largely unknown, although the environmental relative to the genetic contribution is substantial. We conducted a scoping review to comprehensively assess the current state of knowledge of the environmental factors present from preconception to early life associated with ASD, and to identify research gaps.

Methods: We searched electronic databases MEDLINE, PsycINFO and ERIC for articles on potential risk factors or protective factors from the physical and social environments associated with ASD and its subclassifications published between 1 January, 2003, and 12 July, 2013. We categorized articles into broad themes: chemical, physiological, nutritional and social factors, based on environmental exposure.

Results: We identified over 50 000 publications, but after ineligible studies were screened out, 315 articles remained. Most of these studies examined physiological factors, followed closely by chemical factors, and to a much lesser extent, nutritional and social factors, associated with ASD. Despite a vast literature and many heterogeneous studies, several risk factors emerged consistently: chemical factors such as traffic-related air pollutants; physiological factors including advanced parental age, preterm birth, low birth weight, hyperbilirubinemia and clustering of pregnancy complications; and maternal immigrant status. Despite extensive research on vaccines, findings overwhelmingly demonstrate no support for an association with ASD.

Conclusion: The lack of consistency, temporality and specificity of associations between environmental factors and ASD remains the largest barrier to establishing causal relationships. More robust research is required to resolve inconsistencies in the literature. Future research should explore underlying mechanisms of associations between the risk factors that we identified and ASD.

Keywords: ASD, autism spectrum disorder, autism, environmental exposure, etiology

Introduction

Autism spectrum disorder (ASD) is a group of neurodevelopmental disorders with varying levels of severity in impairment in social communication and interaction, and restricted repetitive behaviours, interests and activities.¹ The number of children with ASD has been rapidly rising in the past decade.² In the US, the number of cases increased by 123% from 2002 to

2010, with an estimated prevalence of 1 in 68 children aged 8 years.³ In Canada, from 2003 to 2010, increases of 70% and 95% were reported in Prince Edward Island and Southeastern Ontario, respectively, with corresponding prevalence of 1 in 106 and 1 in 63 children aged 6 to 9 years in 2010.⁴ Greater ASD awareness and changes in diagnostic criteria may be contributing factors,⁵ but explain only a portion of the increased prevalence.^{6,7} Although the

Highlights

- The environmental factors most commonly studied in association with ASD were physiological and chemical factors. Research on nutritional and social factors is limited.
- Older parental age, low birth weight, premature birth, neonatal jaundice and clustering of pregnancy complications were consistently reported to be associated with ASD.
- Evidence for the association between traffic-related air pollutants and ASD has been emerging.
- Maternal immigrant status was consistently associated with ASD.
- The lack of consistency, temporality and specificity of associations between environmental factors and ASD remains the largest barrier to establishing causal relationships.

genetic contribution to the etiology of ASD is known,⁸ the rapid increase in ASD prevalence cannot be fully attributed to genetics alone.

A twin concordance study has shown that shared environmental factors account for 58% of the variance in liability for ASD.⁸ Furthermore, prenatal and early infancy periods are known to be critical periods of growth during which children are particularly vulnerable to harmful effects of environmental hazards that can result in childhood diseases.⁹ However, the role of environmental factors in the onset of ASD is still largely unknown. Of the reviews that have explored possible risk factors of ASD to date,^{10–16} none have comprehensively examined the entire scope of the environmental contribution to ASD.

The purpose of this scoping review is to comprehensively assess the current state of knowledge of environmental factors associated with ASD incidence and to identify research gaps. Specifically, we aim to identify any environmental exposures, including chemical, physiological, nutritional and social factors, from pre-conception to early-life periods associated with ASD.

Methods

This review followed Arksey and O'Malley's scoping framework.¹⁷ We searched the electronic databases MEDLINE, PsycINFO and ERIC for primary studies or reviews on potential modifiable risk factors or protective factors from the physical or social environment associated with ASD. We developed a comprehensive list of medical subject headings and keywords with the help of a librarian at the University of Ottawa. Search terms were centred on two main concepts: (1) ASD and its subclassifications, including pervasive development disorder not otherwise specified (PDD-NOS), autism and Asperger syndrome; and (2) environmental exposures or risk factors, maternal condition before or during pregnancy, and paternal preconception condition. The search strategy was adapted appropriately to the other databases, PsycINFO and ERIC, using their corresponding subject heading terms. Searches were limited to articles with an abstract published in the English language with a publication date between 1 January, 2003, and 12 July, 2013, to focus on current literature. We excluded articles if the epidemiological associations they described included comorbidities, the result of living with ASD or biochemical pathways not directly related to etiology; we also excluded studies that used animal models, cell studies and strictly genetic studies. Commentaries, editorials, letters, news articles and articles that did not primarily focus on ASD etiology were also filtered out.

We categorized journal articles into broad themes: chemical, physiological, nutritional, social and other, based on the nature of the environmental exposure examined. Within each broad theme, we identified recurring subthemes. We abstracted publication year, study design, study population, exposure, confounders, case definition and main findings from each full-text article. The review process

resulted in 315 articles for final analysis (Figure 1). Our review focussed mainly on primary studies and systematic reviews.

Results

The literature encompassed a wide scope of research investigating potential environmental risk factors associated with ASD. Research has been conducted worldwide; many studies were concentrated in the Nordic countries, the United States, the United Kingdom, Australia and Japan. Most studies examined physiological factors, followed closely by chemical factors, and then nutritional and social factors associated with ASD (Table 1; Figure 2). There was some overlap between these areas as several studies examined a combination of factors; about 14% of the articles (44/315) explored more than one theme. The largest proportion of these examined chemical and nutritional factors (heavy metal exposures and mineral deficiencies). Figure 3 shows the frequency of articles published, by research area and publication period. Most articles were published between 2009 and 2013, with the exception of articles on vaccines, most of which were published between 2003 and 2008.

Chemical dimension

The chemical factors we investigated in association with ASD included environmental chemicals, vaccines, medication and substance abuse. Articles on exposure to environmental chemicals and vaccines (both primarily concerning postnatal exposure) each accounted for approximately 40% of the chemical dimension (Figure 2).

Environmental chemicals

The environmental chemicals we examined in association with ASD were predominantly heavy metals, found in biological samples from children, followed by air pollutants; both mainly investigated in case-control studies (Table 2). A small number of the studies and/or reviews explored associations with prenatal or perinatal exposure to occupational chemicals^{18,19} and pesticides.^{20,21}

Heavy metals

Many studies examined biomarkers of postnatal exposure to heavy metals, particularly mercury, in children with ASD or autism compared to children without ASD. Assessing baby teeth, particularly

tooth enamel, which begins to form in utero and continues up to one year after birth,²² can also help determine prenatal exposure. The five most commonly studied heavy metals were mercury, lead, cadmium, aluminum and arsenic.

Mercury: biomarkers and sources of exposure

Mercury has received considerable attention because of the similarities in the symptoms of mercury poisoning and autism.²³ Biomarkers of mercury exposure in children with autism were primarily examined by measuring levels in hair (14 studies), blood (4), urine (4), teeth (2) and nails (1). However, findings were largely inconsistent (Table 3). Urinary porphyrins, intermediates in heme biosynthesis, have also been studied as potential biomarkers for mercury exposure in people with autism, as increased porphyrins have been associated with prolonged mercury exposure.²⁴ Elevated porphyrins have been found in children with autism compared to children without autism,²⁵⁻²⁹ and may increase with severity of autistic symptoms.^{30,31} Although nearly all studies attributed these findings to mercury exposure, none actually measured mercury exposure except for one study, which found no association with ASD despite finding a correlation between elevated porphyrins and ASD.²⁷

Few of the studies in this review investigated mercury exposure from sources other than thimerosal in vaccines and Rh immune globulins. Ecological studies have demonstrated an association between environmentally released mercury emissions and significant increases in autism rates,³² which may be related to residential distance from mercury pollution sources such as industrial or power plant facilities.³³ Other studies have examined other prenatal and postnatal mercury exposure sources in relation to ASD, such as maternal dental amalgam fillings^{27,34,35} and maternal or child consumption of seafood,^{27,36,37} with inconsistent findings.

A 2012 systematic review concluded that, due to methodological issues such as small sample size and inconsistent case ascertainment, the relationship between mercury exposure and ASD remains unclear.³⁸ Furthermore, according to a meta-analysis, hair mercury analysis may not be reliable.³⁹ The use of blood or hair mercury levels as accurate measures of

^a 124 unique studies. Two studies used the same data.

prenatal and early-life exposure is questionable³⁸ considering mercury’s relatively short half-life.^{40,41}

Other heavy metals

Sixteen studies examined the association between exposure to other heavy metals and ASD or autism by measuring levels mainly in hair samples. Lead, cadmium, aluminum and arsenic were the most-studied heavy metals in children with ASD or autism, but there were conflicting findings (Table 3). Most studies found no significant association between aluminum and ASD. None of these studies investigated possible exposure sources.

Pollutants

Only a few studies investigated the relationship between drinking water content

and autism.^{42,43} However, five population-based case-control studies, mostly in California, investigated air pollutant exposure while controlling for sociodemographic factors. Relatively consistent evidence for an association between prenatal, perinatal and/or early-life traffic-related air pollutant exposures and ASD or autism was found⁴⁴⁻⁴⁸ (Table 4). Exposure to traffic-related air pollution can result in respiratory and cardiovascular disease and certain neurological outcomes by triggering inflammation and oxidative stress,⁴⁹⁻⁵¹ which are common physiological abnormalities observed in children with ASD. Maternal residence in areas with higher levels of exposure to nitrogen dioxide,^{44,47} exposure to particulate matter less than 2.5 µm^{44,47} and exposure to nitric oxide⁴⁴

FIGURE 2

during gestation and/or the early life of the child were associated with having a child with autism. Also, residing near a freeway during pregnancy, especially during the third trimester, was associated with having children with autism.⁴⁶ Findings for prenatal exposure to other pollutants including ozone and particulate matter less than 10 µm^{44,47} or prenatal and/or perinatal exposure to specific chlorinated solvents and metals^{45,48} in relation to autism or ASD have been inconsistent so far.

Vaccines and medication

Vaccines

Measles Mumps Rubella (MMR) vaccination

Since the publication of the Wakefield case series study,⁵² which found an increased prevalence of a new variant of autism characterized by gastrointestinal disorders and developmental regression, the safety of MMR vaccine has been questioned, although this paper was later retracted due to false data. Nine case-control and two time-series studies⁵³⁻⁶³ and two systematic reviews^{64,65} found no significant association between MMR vaccine and

ASD or autism, although another time-series study did.⁶⁶ A systematic review found that studies with the lowest bias based on study quality criteria did not support a causal association.⁶⁴ Evidence for an association between the new variant form of ASD^{58,59,65} and MMR vaccine, and between measles infection and autism,^{61,67} was also lacking.

Thimerosal-containing vaccines and immune globulins

Thimerosal, a preservative that contains 50% ethylmercury and is used for multivalent vaccines such as the diphtheria-tetanus-pertussis vaccine, has been widely researched because of concerns about mercury overexposure stemming from the expansion of childhood vaccination schedules in the past several decades. Thimerosal in Rh immune globulins given to pregnant women with Rh incompatibility issues has also been investigated as a source of prenatal mercury exposure.

Postnatal thimerosal exposure: early childhood vaccines

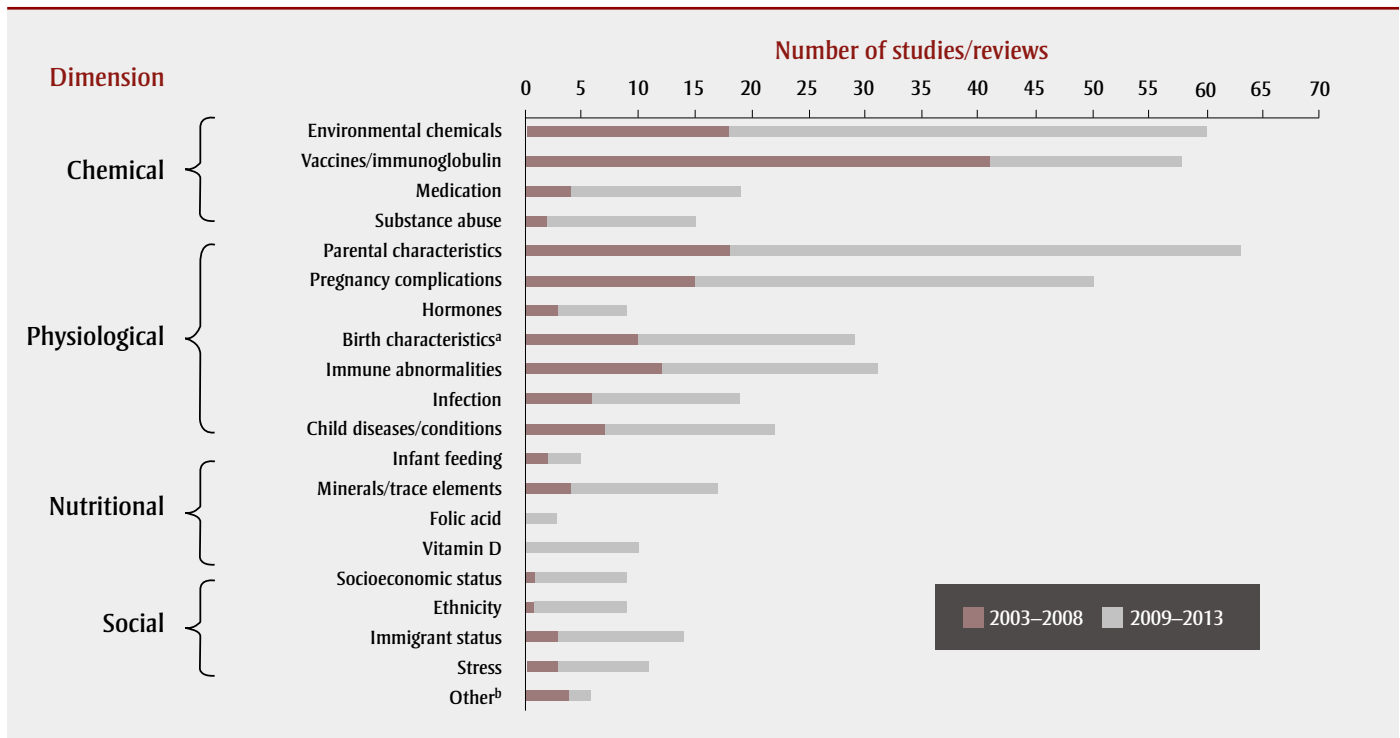

Seven studies demonstrated no significant association between thimerosal-containing

childhood vaccines and ASD,⁶⁸⁻⁷⁴ while four studies did.^{66,75-77} However, most of the studies that supported an association, which all came from the same authors, did not control for potential confounders such as the child's age and sex, in contrast to most studies that found a null association. Both cohort studies that found significant positive associations used the Vaccine Adverse Events Reporting System database, which has been criticized as potentially biased and unreliable because anyone can report an adverse event after vaccination and diagnoses are not medically validated.⁷⁸ Furthermore, no association has been found between autoimmune markers and autism in children given thimerosal-containing vaccines.^{79,80}

Prenatal thimerosal exposure: Rh anti-D immune globulin

Some studies, mostly larger case-control studies, refuted the association between maternal prenatal exposure to thimerosal-containing Rh immune globulin and ASD, adjusting for maternal and/or birth characteristics,^{37,69,81,82} while others found significant

associations without adjusting for potential confounders.^{83,84}

Medication

The increasing use of antidepressants, antibiotics⁸⁵ and acetaminophen⁸⁶ has sparked hypotheses of possible links with the use of these medications and synchronous rising ASD prevalence in the 1980s.

Research on selective serotonin reuptake inhibitors (SSRIs; a class of antidepressants) in relation to ASD has emerged recently, with reviews indicating biologically plausible evidence of an association from animal and preclinical studies.^{87,88} Two case-control studies found a moderate association between prenatal use of SSRIs and ASD.^{89,90} However, if the relationship was causal, prenatal antidepressant use would account for fewer than 1% of ASD cases.⁹⁰

Three reviews cited several clinical studies that provided evidence for increased ASD prevalence among children exposed to valproic acid (or valproate), a teratogenic broad spectrum antiepileptic drug and mood stabilizer, in early pregnancy compared to unexposed children.^{91–93} Additionally,

a large prospective cohort study showed that prenatal valproate exposure was associated with an absolute risk of ASD of 4.42% over a 14-year period among those exposed.⁹⁴

Some studies suggested a possible link between prenatal or early-life antibiotic use and autism.^{85,95,96} Studies found ecological associations with prenatal use of acetaminophen⁹⁷ and circumcision rate (a proxy for acetaminophen, which was widely used following circumcision),⁹⁷ and an association with acetaminophen use following MMR vaccination.⁹⁸ Biologically plausible mechanisms related to the endocannabinoid system affecting central nervous system (CNS) development^{98,99} or impaired detoxification ability upon overdose⁸⁶ have been suggested.

Substance use

Tobacco smoke

A meta-analysis has indicated no significant association between smoking during pregnancy and ASD.¹⁰⁰ Likewise, no association was found in later studies.^{101–105} However, an association between maternal smoking during pregnancy and

subclassifications of ASD, including Asperger syndrome and/or PDD-NOS, has been demonstrated.^{106–108} Maternal second-hand tobacco exposure may be associated with ASD or autism in children based on two small case-control studies.^{37,109}

Alcohol

Two studies, including a prospective cohort study, found no association between prenatal alcohol consumption and ASD or autism,^{106,110} whereas a significant association with heavy prenatal consumption was evident in a small clinic sample.¹¹¹

Physiological dimension

The physiological dimension encompasses many recurring themes related to the physiology of the parents and the child with ASD. Parental characteristics, particularly parental age, and pregnancy complications, especially low birth weight and prematurity, have been the most-studied risk factors for ASD (Table 5).

Parental characteristics

Parental age

Five systematic reviews supported the association between advanced parental

age and ASD.^{13,100,112-114} A 2011 meta-analysis found a pooled odds ratio (OR) for autism of 1.78 (95% confidence interval [CI]: 1.52–2.07) for fathers 40 to 49 years of age compared with fathers aged 29 years or younger.¹¹³ Since the latest systematic review,¹³ four studies have found a significant association with ASD or autism,¹¹⁵⁻¹¹⁸ whereas one did not.¹¹⁹ De novo mutations and genomic copy number variations burden have been implicated as possible underlying mechanisms, because they increase with paternal age.^{120,121} No association has been found between men with autistic-like traits and delayed parenting.^{122,123}

A 2012 meta-analysis found the relative risk (RR) of ASD for mothers aged 35 years or over compared to those aged 25 to 29 years to be 1.31 (95% CI: 1.19–1.45).¹¹⁴ Since the most recent systematic review,¹¹⁴ four studies have found significant associations between advanced maternal age and ASD^{117,118,124,125} and one did not.¹⁰⁶

Some studies have found paternal and maternal ages to be independent risk factors for ASD after adjusting for spousal age,¹²⁶⁻¹²⁸ and no evidence for a synergistic effect.¹¹⁷ Other studies have accounted for multicollinearity of maternal and paternal ages and found that advanced maternal age was the primary independent contributor of the parental age effect.^{118,129,130}

Assisted conception

Assisted conception and ASD share risk factors such as high parental age, high rate of prematurity and low birth weight.¹³¹ A systematic review cited methodological limitations as the source of inconsistent findings for the association between assisted conception and ASD.¹³² Since then, two studies have found a positive association between assisted reproductive technology use and ASD,^{133,134} whereas five studies have found none.^{131,135-138} However, significant positive associations were found among subgroups such as women over age 34,¹³⁶ multiple births¹³⁷ and those exposed to specific assisted conception methods.^{131,135}

Maternal chronic diseases and conditions

Some evidence exists for associations between maternal chronic conditions such as weight gain, obesity and diabetes and ASD. Two^{109,139} of four studies found a positive association between maternal chronic conditions (aggregate measure)

and ASD or autism.^{106,109,139,140} Two^{141,142} of three cohort studies¹⁴¹⁻¹⁴³ found a significant association between either prepregnancy weight, pregnancy weight gain or early-life obesity and ASD. A 2009 meta-analysis found a positive association between maternal gestational diabetes and ASD.¹⁰⁰ Since then, there have been conflicting findings,^{102,124,139,141,144,145} although some of these studies did not differentiate between prepregnancy and gestational diabetes.

Hormones

Prenatal testosterone

An association between elevated prenatal testosterone levels and ASD or autism has been implicated in a review of three meta-analyses¹⁴⁶ and a case-control study.¹⁴⁷ However, no significant correlation was found with neonatal testosterone levels in a cohort study.¹⁴⁸

Thyroid hormone

Thyroid dysfunction, whether due to prenatal or early-life exposure to the anti-thyroid effects of heavy metals, to endocrine-disrupting chemicals or to dietary deficiencies, may affect neurodevelopment.¹⁴⁹⁻¹⁵¹ However, evidence for the association between neonatal or maternal levels of thyroid hormone and ASD is limited and inconsistent.¹⁵²⁻¹⁵⁴

Pregnancy complications

A 2012 systematic review found perinatal and neonatal pregnancy complications to be significantly associated with ASD.¹³ However, findings were inconclusive for eclampsia and/or pregnancy-induced hypertension. Findings were also inconsistent among several other studies.^{102,103,124,125,145,155,156}

Birth weight and gestational age

Two systematic reviews^{112,157} found low birth weight to be a significant risk factor for ASD in children; one of them, a meta-analysis, found a risk ratio (RR) of 1.63 (95% CI: 1.19–2.33).¹⁵⁷ However, a more recent systematic review¹³ indicated mixed findings. Since then, three¹⁵⁸⁻¹⁶⁰ of five studies^{106,109,158-160} have found a significant association between low birth weight and ASD. In most studies, the low birth weight threshold was 2500 g.

Two^{13,112} of three systematic reviews^{13,112,157} supported the association between low gestational age and ASD. Since the 2012 systematic review,¹³ most studies have provided more evidence for this

association^{145,159,161-163} although two studies did not.^{106,125} Based on the positive studies and the systematic review,¹³ the effect estimates for ASD or autism ranged from 1.4 to 4.7. The 37-week cut-off to define “pre-term” births and the 32-week cut-off to define “extremely preterm” births were used in many studies.

Systematic reviews^{13,157} along with subsequent studies^{159,164} have also found a

significant association between small for gestational age and ASD. Other studies have suggested that a deviance in fetal growth¹⁶⁵ and physical development¹⁴⁰ may be associated with ASD onset.

Clustering of pregnancy complications

Eleven studies, including four cohort studies, found clustering of pregnancy complications to be significantly associated with ASD,^{102,104,106,109,124,141,143,166-169} and only one

case-control study did not.¹⁴⁰ Four systematic reviews also supported this association,^{13,100,112,157} with a general consensus that the presence of multiple factors is associated with ASD. However, the types of pregnancy complications examined vary by study. Many studies have explored the association between optimality scores (composite measures of compromised prenatal, perinatal and neonatal health overall) and ASD. Systematic reviews^{100,157}

have found that reduced prenatal and neonatal optimality is more evident than perinatal suboptimality in ASD cases. However, since those reviews, a prospective cohort study has found that having at least four obstetric suboptimality factors (mainly prenatal and perinatal) in the first birth were significantly correlated with ASD.¹²⁴ Three other studies have found that suboptimal birth conditions^{101,105,141} and/or prenatal pregnancy complications^{102,106,141} were more common in children with ASD than in children without ASD.

Systematic reviews^{112,157} have implicated fetal hypoxia (intrauterine deprivation of oxygen) in ASD etiology, based on several perinatal factors that may serve as markers of hypoxia, including low Apgar score,

caesarean section and growth retardation. However, fetal hypoxia has been weakly associated with ASD according to a population-based cohort study.¹⁷⁰

Birth characteristics

Birth order and spacing

Systematic reviews agree that first-born children are more likely to be diagnosed with ASD than children born third or later;^{13,100} the meta-analysis found a 61% increased risk of autism for first-born children compared to children born third or later.¹⁰⁰ This is also consistent with more recent studies,^{106,140,171,172} one of which investigated only Asperger patients.¹⁷¹ Suboptimal parity (giving birth more than two times) has been associated with ASD.¹²⁴ Earlier birth order and greater

parity appear to be conflicting risk factors, because first-born children in sibship sizes of two, and later-born children in families with larger sibship sizes, are more likely to have ASD.¹⁰⁰ In addition, some studies have indicated that ASD symptom severity may be related to birth order, although these studies did not agree on which place in the birth order was more associated with severe symptoms,^{173,174} possibly because interpregnancy intervals may also be a factor.¹⁷⁴ Interpregnancy intervals of less than 18 months¹⁴¹ or less than a year have also been associated with autism in the second-born child.¹⁷⁵

Other birth characteristics

Multiple births have been associated with ASD according to a meta-analysis¹⁵⁷ as

well as a cohort study,¹⁷⁶ whereas an ecological study did not find an association.¹⁷⁷ A meta-analysis also found a significant association between summer births and ASD.¹⁵⁷ However, conflicting findings are evident in several studies.^{144,178-181}

Immune abnormalities

According to a review of research trends, immune dysregulation has been widely studied and possesses the strongest evidence base of the physiological abnormalities in ASD.¹² Early evidence found a

potential link between ASD and two main types of immune dysfunction: autoimmunity and brain inflammation.¹⁸² In addition, significantly reduced neonatal blood immunoglobulin G has been observed in archived specimens from newborns subsequently diagnosed with ASD relative to

newborns not subsequently diagnosed with ASD.¹⁸³

Autoimmune diseases

Several studies have examined the role of autoimmunity in ASD. Three case-control studies have consistently demonstrated that antibody reactivity to human fetal brain protein is more prevalent in mothers of children with ASD or specifically autism than in mothers of children who do not have ASD or specifically autism.^{184–186} Additionally, there may be increased serum folate receptor autoantibodies in children with low-functioning autism with or without neurological deficits relative to control subjects without autism.¹⁸⁷ This suggests that folate transfer to the fetus during pregnancy may be blocked, which may increase risk of neural tube defects.¹⁸⁸ Because these elevated autoantibodies were also present in at least one parent of children with autism, parental antibodies may contribute to autism etiology.¹⁸⁹

Two cohort studies and a case-control study found an association between maternal or family history of autoimmune diseases and ASD^{124,190} or autistic regression,¹⁹¹ whereas another case-control study found no association.¹⁹² However, the specific autoimmune diseases associated with ASD varied by study. Reviews have discussed growing evidence for the role of autoimmunity in ASD, stemming mostly from animal models and human clinical studies, but have indicated a need to identify the functions of the autoantibodies that might be affecting neurodevelopment.^{193–196}

Brain inflammation

Brain inflammation has also been implicated in the etiology of ASD. According to the reviews based mainly on animal and human clinical studies, early-life immune insults such as toxic substances, food additives or stress may result in a cascade of excitotoxicity in the brain,^{197–199} and may be related to dysregulation of glutamate neurotransmission.^{199,200} This cascade may trigger production of proinflammatory cytokines, resulting in chronic inflammation affecting neurodevelopment.

Emerging evidence, mostly from case-control studies, has shown that increased proinflammatory cytokine production is found in the serum or cerebrospinal fluid of ASD children or the amniotic fluid of their mothers,^{201–203} although a decreased neonatal level of cytokines has also been

observed.²⁰⁴ Significantly altered adaptive cellular immune function in children with ASD may reflect defective immune activation, which may in turn be associated with ASD impairment.²⁰³ Also, no significant differences have been reported for levels of certain chemokines in neonatal blood and amniotic fluid,^{201,205} except in a subgroup with an ASD diagnosis based on the most recent diagnostic criteria.²⁰¹

Infection

Infections may trigger the chronic inflammation of the CNS, affecting brain development and maturation, which has been implicated in ASD etiology.¹⁹⁸ However, according to a meta-analysis¹⁰⁰ and 2012 literature review,²⁰⁶ there was no significant association between maternal infection and ASD. A 2012 systematic review indicated that more research is required to explore this association.¹³ Since then, only one case-control study found a significant association,¹⁰⁶ whereas one cohort and three case-control studies did not.^{96,125,140,207} The definition of maternal infection varies across studies; it may encompass any infection during pregnancy, or only specific infections such as influenza.²⁰⁷ Some studies have suggested maternal fever during pregnancy²⁰⁷ or extended febrile episodes⁹⁶ are associated with ASD, although findings are mixed.^{145,208}

Associated child diseases

Neonatal jaundice

Neonatal jaundice, a result of elevated serum bilirubin levels (hyperbilirubinemia), has been a concern because unconjugated bilirubin can be toxic to the developing CNS. Five studies^{125,144,209–211} and two systematic reviews^{13,157} investigated this risk factor. According to the systematic reviews, hyperbilirubinemia was associated with an increased risk of autism^{13,157} with a summary effect estimate of 1.87 (95% CI: 1.01–3.47), according to the meta-analysis.¹⁵⁷

Epileptic disorders

While a meta-analysis indicated no significant relationship between neonatal seizures and ASD,¹⁵⁷ four small studies have provided some evidence for a possible association.^{125,212–214}

Oxidative stress

According to a review of research trends, oxidative stress was one of the most-studied physiological abnormalities in ASD, with one of the strongest evidence bases, mainly consisting of clinical and animal studies.¹² Six case-control studies

indicated a role for oxidative stress in ASD patients^{29,30,215-218} based on different biomarkers of oxidative stress and impaired antioxidant systems. Biomarkers included altered levels of oxidative stress defence systems, including metallothioneins and antioxidant enzymes.²¹⁵ Other markers of oxidative stress, associated heavy metal toxicity and/or low detoxification capacity included abnormal markers of thiol metabolism,²¹⁶ transsulfuration abnormalities,³⁰ urinary organic acids,²⁹ and increased lead and potassium ions, ATPase activity and lipid peroxidation products.²¹⁷

Nutritional dimension

Deficiencies in minerals and levels of trace elements were the most-studied of the nutritional factors in association with ASD, followed by vitamin D deficiency (Table 6).

Minerals and trace elements

Evidence for mineral deficiencies and levels of trace elements in children with ASD or specifically, autism, comes mainly from case-control studies examining hair samples and remains inconclusive. Studies looking at associations between levels of zinc,^{37,95,215,219-223} iron,^{37,215,216,219,222-224} magnesium,^{37,219,220,222,223} copper,^{37,215,216,219,220,222,223,225,226} molybdenum,^{37,219,222,223,225} nickel,^{215,219,222,223,225} and selenium^{37,219,220,223,225} and ASD have had conflicting results. Calcium deficiencies have also been documented in association with ASD or autism in children,^{219,222,223,227} with some inconsistencies.^{37,215} Despite inconsistencies, differences in the levels of cobalt,^{37,215,222,223,225,226} chromium^{37,215,222,223,225,228} and manganese^{37,215,219,223,225,226,229} in children with and without ASD or autism were mostly nonsignificant.

Folic acid	2	1

Note: There is some overlap of subthemes across different studies/reviews.

Vitamin D

Vitamin D plays a crucial role in various functions, such as neurodevelopment, the anti-inflammatory response and the detoxification pathway.^{230,231} However, evidence for an association between vitamin D deficiency and ASD is limited and indirect. Two ecological studies^{63,232} and a case-control study²²⁷ have indicated an association between vitamin D deficiency in mothers and/or their children with autism, and the onset of autism. It has been suggested that migration may play a role in the etiology of ASD, because of increased autism prevalence rates among immigrants in northern European countries, and because immigrants with dark skin are more prone to vitamin D deficiency due to their skin pigmentation.²³³ However, both a small case-control study²³⁴ and a recent Australian prospective cohort study²³⁵ found no significant association between maternal serum vitamin D levels and ASD or a majority of autistic-like traits in their offspring. Furthermore, a systematic review concluded that there was inadequate support for an association, and that more population-based longitudinal studies are needed, given the plausible biological evidence.²³⁰

Infant feeding

We found few studies on infant feeding methods in relation to ASD, although two case-control studies found that the absence or late initiation of breastfeeding was significantly associated with ASD or autism,^{236,237} in contrast to findings of an ecological study.⁶³

Folic acid

Evidence supporting an association between folic acid intake and ASD is very sparse, although a recent prospective cohort study found maternal folic acid intake to be protective against ASD,²³⁸ in contrast to an ecological study that found positive correlations between the percentages of prescription prenatal vitamins and pediatric vitamins containing folic acid and ASD incidence.²³⁹

Social dimension

Socioeconomic status (SES), ethnicity, immigrant status and stress were recurring social factors examined in association with ASD (Table 7).

Socioeconomic status

The importance of SES emerged as a predictor of ASD risk in nine studies,^{102,119,172,240-245} but findings were mixed. Mainly in American studies, a higher SES, using proxies such as maternal income, occupation and education, was associated with ASD.^{172,240-242} However, when researchers in one of these studies conducted a subanalysis by case ascertainment, no association with SES was found using case ascertainment only from school sources.²⁴² In an Australian study,¹⁷² maternal residence in remote areas was negatively correlated with cases of ASD without intellectual disability (ID). However, other studies had different results.^{102,119,243,244} In countries with universal health care programs, such as Sweden and Canada, lower family or maternal income was associated with ASD, which suggests that the associations between high SES and ASD found mainly in the US studies may reflect inequalities in access to health care services (e.g. under-diagnosis of ASD in families with lower SES).^{102,244} Furthermore, spatial analysis of autism incidence in regions of California indicated a higher incidence that was independently characterized by higher levels of parental education.²⁴⁵

Ethnicity

Most studies that examined the relationship between maternal ethnicity and ASD found a significant association,^{102,119,172,242,243,246} with the exception of one study in the United Kingdom.²⁴⁷ In particular, maternal minority ethnic status, such as Aboriginal status, was associated with reduced ASD diagnosis in offspring^{102,119,172,243} with an OR ranging from 0.33 to 0.83 for certain non-White ethnic groups compared to White, non-Hispanic people. Furthermore, children who were Black, Hispanic or

“other” race/ethnicity were less likely than White children to have ASD, which was more pronounced in children with ID for some ethnic groups, according to an American study.²⁴⁶ The finding that minority groups would be less likely to be diagnosed with ASD may be due to ascertainment bias. Differential assessment of children’s intellectual and developmental problems may account for these ethnic disparities. In contrast, another American study found that Black race was associated with increased odds of ASD, particularly with ID, but case ascertainment was more likely from school sources.²⁴² These studies suggest possible racial or ethnic disparities in ASD diagnosis such that for some groups, comorbid ID may affect its detection.

Immigrant status

Maternal immigrant status is another social factor that emerged in eight studies^{104,208,243,247-251} and two systematic reviews^{13,100} supporting an association with ASD or ASD subtype. Migrant mothers had a higher prevalence of offspring with ASD in studies from Sweden, the United Kingdom and Australia. The meta-analysis found a marginal association between maternal immigrant status and autism (summary effect estimate = 1.28; $p = .06$).¹⁰⁰ However, among Nordic countries, the association was statistically significant, with a 58% increased risk among children whose mothers were born abroad.¹⁰⁰ According to a Swedish study, migrant parents from countries with a low ranking on a human development index may be at increased risk of having children with ASD and comorbid ID compared with Swedish-born parents, particularly when migration occurred around time of pregnancy, suggesting a possible link with maternal stress.²⁴⁹ However, migrant parents from developing countries may have a decreased risk of having children with PDD-NOS or Asperger.²⁵⁰ Sociopolitical context such as changes in immigration policy has also been shown to influence trends in autism diagnosis rates. For example, a decline in autism rates among Hispanic children in the United States was attributed to undocumented immigrant parents’ reluctance to seek diagnostic services due to fears of being reported to the authorities and having to face deportation when threatened by anti-immigrant policy enforcement.²⁵¹

Maternal stress

Prenatal exposure to environmental stressors, including stress-related immunological and neuroinflammatory abnormalities and placental dysfunction that can affect fetal neurodevelopment, may play a role in ASD etiology.^{252,253} A 2012 systematic review indicated this association requires more study to provide conclusive evidence.¹³ Since then, one cohort study and a case-control study have shown that maternal stress during pregnancy is associated with conceiving a child with ASD,^{106,254} whereas three other case-control studies did not find an association.^{140,145,255} In many of these studies, “stressors” may be defined broadly as any type of stressful event,^{106, 140,145,255} or specifically as certain stressful events such as early-life childhood abuse.²⁵⁴

Other

In addition to the chemical, physiological, nutritional and social dimensions, several other factors emerged that were investigated for association with ASD. Two studies showed that autism births occur in geographical clusters, which could indicate that local factors are involved in the prevalence.^{247,256} Another study found that while electromagnetic radiation has been hypothesized to be a risk factor due to biological plausibility, no epidemiological evidence is yet available.²⁵⁷ Other studies have found no significant association between prenatal exposure to ultrasound and ASD.^{256,258}

Discussion

Most of the research on the environmental contribution to ASD etiology focussed on physiological or chemical risk factors, and less on social and nutritional factors. Within these dimensions, however, the vast literature is riddled with inconsistent findings. Heterogeneity is evident in study populations, exposure and outcome assessment, changing diagnostic criteria and/or ASD phenotypes, all of which vary between studies and may affect the validity of findings.

Biomarkers of heavy metal exposure, particularly mercury, from levels measured in biological specimens such as hair, blood and urine have been studied intensely, but its association with ASD remains uncertain due to conflicting findings. Because most of these studies only measure biomarkers of heavy metal, and do not ascertain

actual exposure sources, temporality of association is unknown. Furthermore, many of the biomarker studies had small sample sizes. These findings are consistent with a recent systematic review by Rossignol and colleagues¹¹ (published in 2014, after the completion of our review), who examined the association between environmental toxicant exposure and ASD.

In contrast, emerging evidence for the association between traffic-related air pollutants and ASD or autism has been relatively consistent, although further research is required to establish specificity of association and improve external validity beyond the American landscape. These findings are also consistent with Rossignol’s review, which found that air pollution is the chemical risk factor with the strongest evidence of an association with ASD, although the association with pesticides was also relatively strong.

Despite numerous studies exploring the relationship between MMR or thimerosal-containing vaccines and ASD, there is a lack of convincing support for this association. Additionally, evidence of an association between fetal or childhood exposure to various medications and ASD is limited to a few studies. A lack of association between tobacco smoke exposure and ASD is also apparent, although some studies have indicated a possible link with PDD-NOS, warranting further study on ASD subgroups separately if causal relationships are to be elucidated. Moreover, studies on exposure to occupational chemicals, pesticides and alcohol were limited.

The most widely and consistently implicated physiological factors in ASD onset include advanced parental age, low birth weight, prematurity and clustering of pregnancy complications. A consistent association between hyperbilirubinemia and ASD has been demonstrated as well. More research is warranted on the effects of advanced grandparental age on ASD, based on preliminary findings.^{115,259} Furthermore, studies are needed to understand the mechanisms for associations between these physiological factors and ASD. Emerging epidemiological evidence for immune abnormalities related to autoimmunity and brain inflammation have also been reported in children with ASD or their mothers. However, further work is

required to establish temporality of association and to elucidate their possible role in ASD etiology.

More research is also needed to understand other physiological factors such as birth characteristics, maternal chronic conditions, hormones and child conditions in relation to ASD. Studies have indicated a potential relationship between chronic conditions such as pregnancy weight gain or maternal diabetes and ASD. However, due to heterogeneity and lack of specificity of exposures, further research is warranted. Evidence for a link between earlier birth order, greater parity and short interpregnancy intervals and ASD exists, although the etiological contribution is not clear. The association between oxidative stress and ASD has been demonstrated by a limited number of small epidemiological studies.

The relationship between nutritional factors and ASD has not been well studied compared to that with chemical and physiological factors. Although several studies investigated associations with mineral and/or trace element deficiencies and vitamin D deficiency, evidence is inconsistent and indirect. For example, maternal foreign birthplace and/or ethnicity were used as proxies for vitamin D concentration, based on the possibly inaccurate assumption that women in these categories would have darker skin pigmentation, affecting their vitamin D concentrations.²³³ More direct evidence for an association between vitamin D and ASD by direct exposure measurements is required.

The current literature suggests that associations between social factors such as SES and ethnicity and ASD may vary across countries, depending on possible case ascertainment biases. However, maternal immigrant status has been consistently correlated with ASD. Whether this may relate to SES, adaptation to a new environment, stress or changes in vitamin D exposure as suggested by some studies requires further investigation.

Overall, the lack of consistency, temporality and specificity of the associations observed in many studies precludes the establishment of causality. Longitudinal studies may be helpful in establishing temporality to identify possible causal relationships. Consistent methods of measuring exposure and case ascertainment

and consideration for potential confounders could reduce heterogeneity. Underlying mechanisms of some of these associations need to be investigated through further biological research.

Strengths and limitations

Of the reviews that have explored possible risk factors of ASD to date, none have examined the entire scope of the environmental contribution to ASD. We conducted a comprehensive, systematic search of the literature. Although all relevant articles may not have been retrieved in this review, a large number of potentially contributing factors were identified that can provide an adequate picture of the breadth of environmental contribution to ASD etiology.

Although the search strategy to retrieve relevant ASD articles aimed for comprehensiveness, key scientific journals were not hand-searched and no searches were performed on citations referenced in included studies and grey literature. Furthermore, more information on environmental factors may have been missed if articles covering them also dealt with animal models or genetic studies, which were excluded. This is evident for research in immune abnormalities and oxidative stress, because articles retrieved were fewer in number although reviews have indicated a vast amount of research, likely from clinical and animal studies. Because the aim of this scoping review was to assess the current state of knowledge of environmental risk factors of ASD, quality assessment of these studies was not performed to assess the strength of evidence.

Conclusion

Our scoping review examined research conducted between 2003 and 2013 on environmental factors potentially associated with ASD, grouped into four categories: chemical, physiological, nutritional and social. We found that physiological factors including advanced parental age, low birth weight, prematurity, hyperbilirubinemia and clustering of pregnancy complications have been consistently reported as risk factors for ASD. While evidence for an association with traffic-related air pollutants is emerging, research on nutritional factors associated with ASD is limited. Of the factors in the social dimension, immigrant status has been consistently associated with ASD, which warrants

further research. Other associations with social factors such as SES and ethnicity may reflect disparities in ASD diagnosis. Large prospective studies, adjusting for sociodemographic confounders, are needed to resolve inconsistencies, especially in the area of heavy metal exposure, where evidence for an association with ASD is still inconclusive.

Because there are a variety of associations with ASD, the etiology is likely multifactorial. Future studies should continue exploring how these different factors may be interrelated. Overall, the lack of consistency, temporality and specificity of associations between environmental factors and ASD remains the largest barrier to establishing causal relationships.
