Cholesterol Efflux Capacity, HDL Particle Number, and Incident Cardiovascular Events:

An Analysis From the JUPITER Trial (Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin)

Abstract

Background—Recent failures of drugs that raised high-density lipoprotein (HDL) cholesterol levels to reduce cardiovascular events in clinical trials have led to increased interest in alternative indices of HDL quality, such as cholesterol efflux capacity, and HDL quantity, such as HDL particle number. However, no studies have directly compared these metrics in a contemporary population that includes potent statin therapy and low LDL cholesterol.

Methods—HDL cholesterol levels, apolipoprotein A-I (apoA-I), cholesterol efflux capacity, and HDL particle number were assessed at baseline and 12 months in a nested case-control study of

Dr. Khera reports funding support from an ACCF/Merck Cardiovascular Research Fellowship, a John S. LaDue Memorial Fellowship in Cardiology from Harvard Medical School, and a KL2/Catalyst Medical Research Investigator Training award from Harvard Catalyst funded by the National Institutes of Health (NIH) (TR001100). Drs. Adelman and Collins are employees of Vascular Strategies. Dr. Glynn has received research grant support from AstraZeneca. Dr. Ridker has received research grant support from AstraZeneca, Novartis, Amgen, Pfizer, Kowa, and NHLBI; he is listed as a co-inventor on patents held by the Brigham and Women's Hospital related to the use of inflammatory biomarkers in CVD (licensed to AstraZeneca and Siemens). Dr. Rader has received consulting fees from Aegerion, Alnylam, Eli Lilly, Pfizer, and Novartis; he is a cofounder of VascularStrategies and Staten Biotechnology. Dr. Mora has received research grant support from Atherotech Diagnostics and NHLBI, and has received consulting fees from Amgen, Lilly, Pfizer, Cerenis Therapeutics, and Quest Diagnostics. Dr. Mora and Dr. Otvos have a patent application on the use of an NMR spectroscopy biomarker unrelated to HDL for predicting risk of colorectal cancer.

the JUPITER trial, a randomized primary prevention trial that compared rosuvastatin treatment to placebo in individuals with normal LDL cholesterol but increased C-reactive protein levels. 314 cases of incident cardiovascular disease (myocardial infarction, unstable angina, arterial revascularization, stroke, or cardiovascular death) were compared to age- and gender-matched controls. Conditional logistic regression models adjusting for risk factors evaluated associations between HDL-related biomarkers and incident CVD.

Results—Cholesterol efflux capacity was moderately correlated with HDL cholesterol, apoA-I, and HDL particle number (Spearman $r=0.39, 0.48, \text{ and } 0.39$ respectively; $P<0.001$). Baseline HDL particle number was inversely associated with incident CVD (adjusted odds ratio per SD increment [OR/SD] 0.69; 95%CI 0.56–0.86; $p<0.001$), while no significant association was found for baseline cholesterol efflux capacity (OR/SD 0.89; 95%CI 0.72–1.10; $p=0.28$), HDL cholesterol (OR/SD 0.82; 95%CI 0.66–1.02; $P=0.08$), or apoA-I (OR/SD 0.83; 95%CI 0.67–1.03; $p=0.08$). 12 months of rosuvastatin (20mg/day) did not change cholesterol efflux capacity (average percent change -1.5% , 95%CI -13.3 to $+10.2$; $p=0.80$), but increased HDL cholesterol ($+7.7\%$), apoA-I ($+4.3\%$), and HDL particle number ($+5.2\%$). On-statin cholesterol efflux capacity was inversely associated with incident CVD (OR/SD 0.62; 95%CI 0.42–0.92; $p=0.02$), although HDL particle number again emerged as the strongest predictor (OR/SD 0.51; 95%CI 0.33–0.77; $p<0.001$).

Conclusions—In JUPITER, cholesterol efflux capacity was associated with incident CVD in individuals on potent statin therapy but not at baseline. For both baseline and on-statin analyses, HDL particle number was the strongest of four HDL-related biomarkers as an inverse predictor of incident events and biomarker of residual risk.

Keywords

cardiovascular disease risk factors; high-density lipoprotein cholesterol

Introduction

High-density lipoprotein (HDL) cholesterol is a well-integrated biomarker of cardiometabolic health and remains a key component of the cardiovascular disease (CVD) risk prediction algorithms used to guide therapy.¹ However, HDL cholesterol-raising therapeutics have failed to demonstrate efficacy in multiple recent clinical trials.^{2–4} These results have called into question both the causality of the observed relationship between HDL and CVD and the hypothesis that modulation of HDL cholesterol levels can improve clinical outcomes. At a minimum, it has become clear that changes in HDL cholesterol levels are an inadequate surrogate biomarker for therapeutic efficacy.

The static measurement of HDL cholesterol levels, as is performed in current clinical practice, may not adequately capture the anti-atherogenic properties of highly heterogeneous HDL particles. Beyond apolipoprotein A-I (apoA-I), proteomics analyses have identified more than 80 distinct proteins associated with circulating HDL particles.⁵ Previous studies have suggested that the number of circulating HDL particles may serve as a better predictor

of cardiovascular risk than HDL cholesterol levels.^{6–13} A putative atheroprotective mechanism of HDL involves the reverse cholesterol transport pathway, the process by which excess cholesterol is removed from the periphery and returned to the liver for biliary excretion.¹⁴ Cholesterol efflux capacity is one metric of HDL functionality that quantifies the ability for an individual's HDL to extract cholesterol from macrophages, the rate-limiting step of reverse cholesterol transport. Efflux capacity was demonstrated to be a better predictor of atherosclerotic burden than HDL cholesterol levels in several previous studies.^{15–19} This inverse relationship was extended to incident cardiovascular events in some,^{16–18} but not all,¹⁹ previous analyses. However, owing to challenges of standardizing a cell-based assay across laboratories, it is unlikely that assessment of efflux capacity will enter into routine clinical use.

Few previous studies have determined the relationships between these various HDL-related biomarkers, and none to-date have directly compared their associations with incident cardiovascular events, particularly in a contemporary cohort with low or normal levels of low-density lipoprotein (LDL) cholesterol levels that includes randomized treatment with potent statin therapy. Here, we examined prospective associations of HDL cholesterol, apoA-I, HDL particle number, and cholesterol efflux capacity in a nested case-control cohort derived from the Justification for the Use of Statins in Prevention: An Intervention Evaluating Rosuvastatin (JUPITER) clinical trial.²⁰

Methods

Study Population

The study population was derived from the JUPITER trial, a previously reported primary prevention, randomized, double-blind, placebo-controlled trial investigating whether rosuvastatin 20 mg daily would decrease incident CVD in 17,802 asymptomatic individuals with LDL cholesterol <130 mg/dL and a high-sensitivity C-reactive protein (hsCRP) level ≥ 2.0 mg/L.²⁰ Exclusion criteria for the JUPITER trial included diabetes mellitus, previous or current use of lipid-lowering therapy, or triglycerides >500 mg/dL. In addition to blood samples required for the trial protocol assays, 11,953 (67%) of trial participants voluntarily provided samples for additional biomarker phenotyping. Endpoints within the JUPITER trial were adjudicated by an independent committee blinded to treatment assignment.²⁰ All participants provided written informed consent as part of the JUPITER trial enrollment. Institutional review board approval for the present study was obtained from Partners HealthCare (Boston, MA).

A nested case-control cohort was derived from individuals with available baseline blood samples. The primary analysis involved 314 cases who experienced the JUPITER trial primary endpoint (myocardial infarction, hospitalization for unstable angina, arterial revascularization, stroke, or cardiovascular death); an expanded secondary endpoint (N = 525 cases) was prespecified to additionally include death from any cause as implemented in previous JUPITER biomarker analyses (Supplementary Table 1).^{21–23} Each case definition was compared to controls who remained free of events at the time of case event and matched in a 1:1 ratio based on age (within two years) and sex.

Laboratory Measurements

Fasting lipids, apolipoproteins, hsCRP, and glucose levels were measured in a core laboratory as previously described.^{20,23,24} HDL particle number was measured using nuclear magnetic resonance (NMR) spectroscopy LipoProfile III, by LipoScience, Inc (now LabCorp, Raleigh, NC). Total particle number was calculated to be the sum of levels across HDL subclasses, identified based on lipid methyl group NMR signals as previously described.¹²

Cholesterol efflux capacity was quantified in plasma samples thawed from liquid nitrogen storage using a previously validated cell-based *ex vivo* assay.¹⁵ In brief, J774 macrophage cells were incubated with ³H-radiolabeled cholesterol. Expression of the ATP-binding cassette transporter A1 (ABCA1) transporter was upregulated using cyclic AMP. Diluted apolipoprotein B-depleted plasma was then added and liquid scintillation counting used to quantify the percent of radioactive cholesterol from the cells effluxed into the media. In order to minimize variation related to batch effects, paired baseline and 12-month samples from cases and matched controls were included on the same plate for efflux capacity assessment. Secondly, a pooled plasma control was used to correct for interassay variation across assays. In a pilot analysis involving blinded duplicate assessments of 20 patient samples divided into two aliquots, the mean intra- and interassay coefficients of variation were 3.7% and 4.7% respectively. Lipoprotein-associated phospholipase A₂ activity levels were measured using an automated enzyme assay system.²⁵ HDL-related phenotypes, including cholesterol efflux capacity, were measured both at baseline and after twelve months of therapy in individuals with samples available.

Statistical Analysis

Medians, 25th, and 75th percentiles were calculated for continuous variables. The significance of variation in cholesterol efflux capacity across categorical patient characteristics was assessed using the nonparametric Wilcoxon rank sum or Chi-square tests. Spearman coefficients were calculated to determine the magnitude of correlation between biomarkers. The impact of treatment on HDL-related phenotypes was determined by calculating the percent change from baseline to 12-months in individuals stratified by treatment group. Statistical comparisons with baseline and placebo values determined via one-sample and two-sample t tests respectively.

Odds ratios were calculated across tertiles as well as per standard deviation increment in each biomarker. Conditional logistic regression models accounting for the matched study design were adjusted for age, race, randomized treatment group, smoking status, systolic blood pressure, body-mass index, fasting glucose, low-density lipoprotein cholesterol level, log-transformed triglyceride level, and family history of premature coronary artery disease. P values for trend were obtained by including tertile number as a variable in the regression model. Models analyzing on-statin biomarkers incorporated on-treatment values for LDL and log-transformed triglycerides. In order to preserve power while maintaining the matched case-control design, subgroup analyses were conducted by adding appropriate interaction terms to the models. Subgroup-specific linear regression parameters and odds ratios were

calculated using combinations of main effect and interaction terms (Supplementary Methods).

All P values were two-tailed with a value < 0.05 used to indicate statistical significance. Analyses were performed using R version 3.1 software (The R Project for Statistical Computing, Vienna, Austria).

Results

The study population included 1050 trial participants—525 controls, 314 cases who experienced the primary JUPITER trial endpoint, and 525 cases who experienced the expanded secondary endpoint inclusive of all-cause mortality (Table 1). Those who experienced the primary JUPITER trial endpoint were more likely to have been allocated to placebo, had slightly lower body-mass index, were more likely to report current smoking, and had higher baseline triglycerides. HDL cholesterol, apolipoprotein A-I, and HDL particle number were each significantly lower in cases compared with controls. By contrast, no significant difference was noted in baseline cholesterol efflux capacity.

Baseline cholesterol efflux capacity was higher in female participants (Table 2), but did not appreciably vary according to treatment group, smoking status, family history of premature coronary artery disease, or the presence of the metabolic syndrome. Moderate correlations were noted between efflux capacity and other HDL-related phenotypes (Figure 1; Supplementary Table 2). LDL-related biomarkers demonstrated modest correlations with cholesterol efflux capacity, with Spearman correlation coefficients of 0.19, 0.15, and 0.18 for non-HDL cholesterol, LDL cholesterol, and apolipoprotein B levels, respectively ($p < 0.0001$ for each). HsCRP and lipoprotein-associated phospholipase A₂ activity levels, biomarkers of inflammation, both demonstrated inverse correlations with efflux capacity (Spearman correlation coefficients -0.09 and -0.21 respectively; $p = 0.003$ and $p < 0.0001$).

Overall, no significant association was found between baseline cholesterol efflux capacity and incident cardiovascular events, with adjusted odds ratios for tertiles two and three compared to tertile one of 1.08 (95%CI 0.70 – 1.67) and 0.75 (95%CI 0.47 – 1.21) respectively. Similarly, the adjusted OR/SD increment in efflux capacity was not statistically significant $- 0.89$ (95%CI 0.72 – 1.10; $p = 0.28$) (Table 3 and Figure 2). No significant heterogeneity of effect was noted according to sex, randomization to rosuvastatin versus placebo, or in participants stratified according to median hsCRP levels, or other clinical subgroups (Supplementary Table 3). The efficacy of rosuvastatin was also similar across tertiles of baseline cholesterol efflux capacity (Supplementary Table 4).

Twelve-month levels of cholesterol efflux capacity were available in 617 of 1,050 (59%) study participants. Rosuvastatin treatment compared with placebo did not lead to a significant change in cholesterol efflux capacity (Table 4). By contrast, a modest increase in HDL cholesterol, apoA-I, and HDL particle number levels was noted in individuals randomized to rosuvastatin treatment, with average percent change values of 7.7, 4.3, and 5.2% respectively (Table 4). Moderate correlations were noted between change in cholesterol efflux capacity and change in HDL cholesterol, apoA-I, and HDL particle

number (Spearman $r = 0.26, 0.36, 0.20$ respectively; $p < 0.001$ for each; Supplementary Table 5). Change in efflux capacity was not related to incident cardiovascular events (adjusted odds ratio per 10% change 0.96; 95% CI 0.88 – 1.04; $p = 0.33$; Supplementary Table 6).

On-statin levels of cholesterol efflux capacity were available for 248 of 450 (55%) of rosuvastatin-treated study participants (Supplementary Table 7). On-statin cholesterol efflux capacity was significantly associated with risk of incident cardiovascular events for the primary endpoint (OR/SD increment 0.62; $p = 0.02$) but not for the expanded endpoint inclusive of total mortality (OR/SD increment 0.79; $p = 0.13$) – Table 5 and Figure 2. No significant heterogeneity of effect was noted across clinical or biomarker parameters (Supplementary Table 8).

Among HDL-related biomarkers assessed at baseline, HDL particle number had the strongest inverse association with incident cardiovascular events, followed by HDL cholesterol and apoA-I levels (Figure 2 and Supplementary Table 9). A similar pattern emerged in the on-statin analysis; although point estimates for all four HDL-related biomarkers suggested an inverse association with incident events, HDL particle number emerged as the strongest inverse predictors of incident events (Figure 2, Table 6, Supplementary Table 10). Effect estimates for baseline and on-treatment associations were similar in a sensitivity analysis that was restricted to cases ($N = 182$) with an incident ‘hard’ cardiovascular event of myocardial infarction, stroke, or cardiovascular death. Importantly, the magnitude of association for these biomarkers compares favorably to that observed for Non-HDL cholesterol, a frequently used surrogate for atherogenic apolipoprotein-B containing lipoproteins. For example, in a model adjusting for age, treatment, race, systolic blood pressure, smoking, BMI, and fasting glucose, the OR/SD lower non-HDL cholesterol of 0.73 (95% CI 0.53 – 1.00; $p = 0.05$) was observed.

Inclusion of alternate HDL-related biomarkers in the same regression model was used to isolate independent predictors of residual risk for incident cardiovascular events (Table 6). In this analysis, the inverse association between HDL particle number levels incident CVD was the most robust and maintained significance in each of the mutually adjusted models.

Discussion

In a nested case-control study in the JUPITER trial of participants with elevated hsCRP but normal or low LDL cholesterol, we determined the relationship between four key markers of HDL metabolism – HDL cholesterol, apoA-I, HDL particle number, and cholesterol efflux capacity – and risk of incident CVD. An inverse relationship was noted for on-statin, but not baseline, cholesterol efflux capacity and incident cardiovascular events. Among all four HDL related phenotypes analyzed, HDL particle number emerged as the strongest inverse predictor of incident events, both at baseline and during potent statin therapy.

Our findings of moderate correlations between cholesterol efflux capacity and HDL cholesterol levels, apoA-I, and HDL particle number are in keeping with multiple previous reports.^{15–17} We extend these observations to note an inverse association between

cholesterol efflux capacity and the inflammatory biomarkers hsCRP and lipoprotein-associated phospholipase A₂ activity. This finding is consistent with previous mouse and human data suggesting that remodeling of the HDL proteome or site-specific oxidation of apolipoprotein A-I by myeloperoxidase in an inflammatory setting inhibits cholesterol efflux and the reverse cholesterol transport pathway.^{26–28}

Rosuvastatin was associated with an increase in HDL cholesterol, apoA-I, and HDL particle number as previously reported,¹² but had no impact on cholesterol efflux capacity, consistent with a similar result noted in a randomized trial involving pravastatin or atorvastatin.¹⁵

In contrast with most previous studies,^{15–18} we did not observe a significant inverse relationship between baseline cholesterol efflux capacity and incident cardiovascular events in JUPITER. One potential explanation for this directionally consistent but less striking relationship may relate to the elevated hsCRP for all JUPITER participants. The drivers of atherosclerotic events in this inflammatory context may be different than those in previous population-based studies.^{15–19} Interestingly, on-statin cholesterol efflux capacity was inversely associated with incident cardiovascular events. This finding could reflect the increased importance of HDL functionality in the context of a very low-achieved LDL cholesterol or during statin therapy. Although not conclusive, this association supports ongoing efforts to incorporate therapies that promote reverse cholesterol transport into statin-based regimens to improve patient outcomes.

The current study findings add to a growing body of evidence supporting HDL particle number as a stronger predictor of incident cardiovascular events than HDL cholesterol or apolipoprotein A-I levels. Similar observations were noted from less contemporary population cohorts^{6–8} and clinical trial-based analyses.^{9–12} In the Women's Health Study, a significant inverse relationship was noted with incident coronary events,²⁹ but not for overall cardiovascular outcomes.³⁰ The present study extends this previous evidence base, noting that HDL particle number was the strongest HDL-related biomarker of residual risk in participants treated with potent statin therapy. Secondly, we note that HDL particle number was a better risk predictor than the best-validated metric of HDL functionality, cholesterol efflux capacity. If confirmed in additional studies, HDL particle number assessment may have value as a surrogate for clinical efficacy in the assessment of interventions targeting HDL metabolism. This NMR-based assessment affords considerable logistical advantages over cholesterol efflux capacity, a cell-based assay that requires significant resources and is difficult to standardize across studies or research groups.

Strengths of the study include detailed assessment of four HDL-related phenotypes in a contemporary clinical trial population, prospective adjudication of all trial endpoints, and the randomized allocation of potent statin therapy to achieve very low levels of circulating LDL cholesterol. A limitation of this study is that the JUPITER trial was terminated after a median follow-up of 1.9 years on the basis of demonstrated efficacy of rosuvastatin therapy in cardiovascular event reduction.²⁰ The relatively small number of CVD events may have limited power to detect associations between HDL related phenotypes and outcomes, particularly in analyses restricted to those receiving rosuvastatin therapy. Furthermore, the

generalizability of our findings may be limited beyond the population studied in the JUPITER trial.

Conclusions

On-statin but not baseline cholesterol efflux capacity was inversely associated with incident cardiovascular events in JUPITER trial participants. Among four HDL-related biomarkers, HDL particle number was the strongest inverse predictor of risk in both baseline and on-statin analyses. Whether a therapy designed to enhance cholesterol efflux capacity or increase HDL particle number can complement high-potency statin therapy in reducing cardiovascular risk remains to be determined.

Clinical Perspective

What is new?

- Moderate correlations between HDL-related biomarkers – HDL-cholesterol, apolipoprotein A-I, HDL particle number, and cholesterol efflux capacity – were noted in JUPITER trial participants, reinforcing the complementary information provided by each assessment.
- No significant relationship was observed between baseline or serial changes in cholesterol efflux capacity (a commonly used measure of HDL functionality) and incident cardiovascular events; however, cholesterol efflux capacity assessed on potent statin therapy was inversely associated with incident cardiovascular events.
- Among HDL-related biomarkers, HDL particle number demonstrated the strongest inverse association with incident cardiovascular events when assessed both at baseline and on potent rosuvastatin therapy.

What are the clinical implications?

- Cholesterol efflux capacity was a marker of residual risk when assessed on statin therapy, consistent with a potential role in driving residual risk in a low LDL-cholesterol environment.
- HDL particle number was a stronger predictor of CVD than other HDL-related biomarkers and may serve as a biomarker of residual risk or response to therapy in the future.
- Whether a therapy designed to enhance cholesterol efflux capacity or increase HDL particle number can reduce cardiovascular risk remains uncertain.

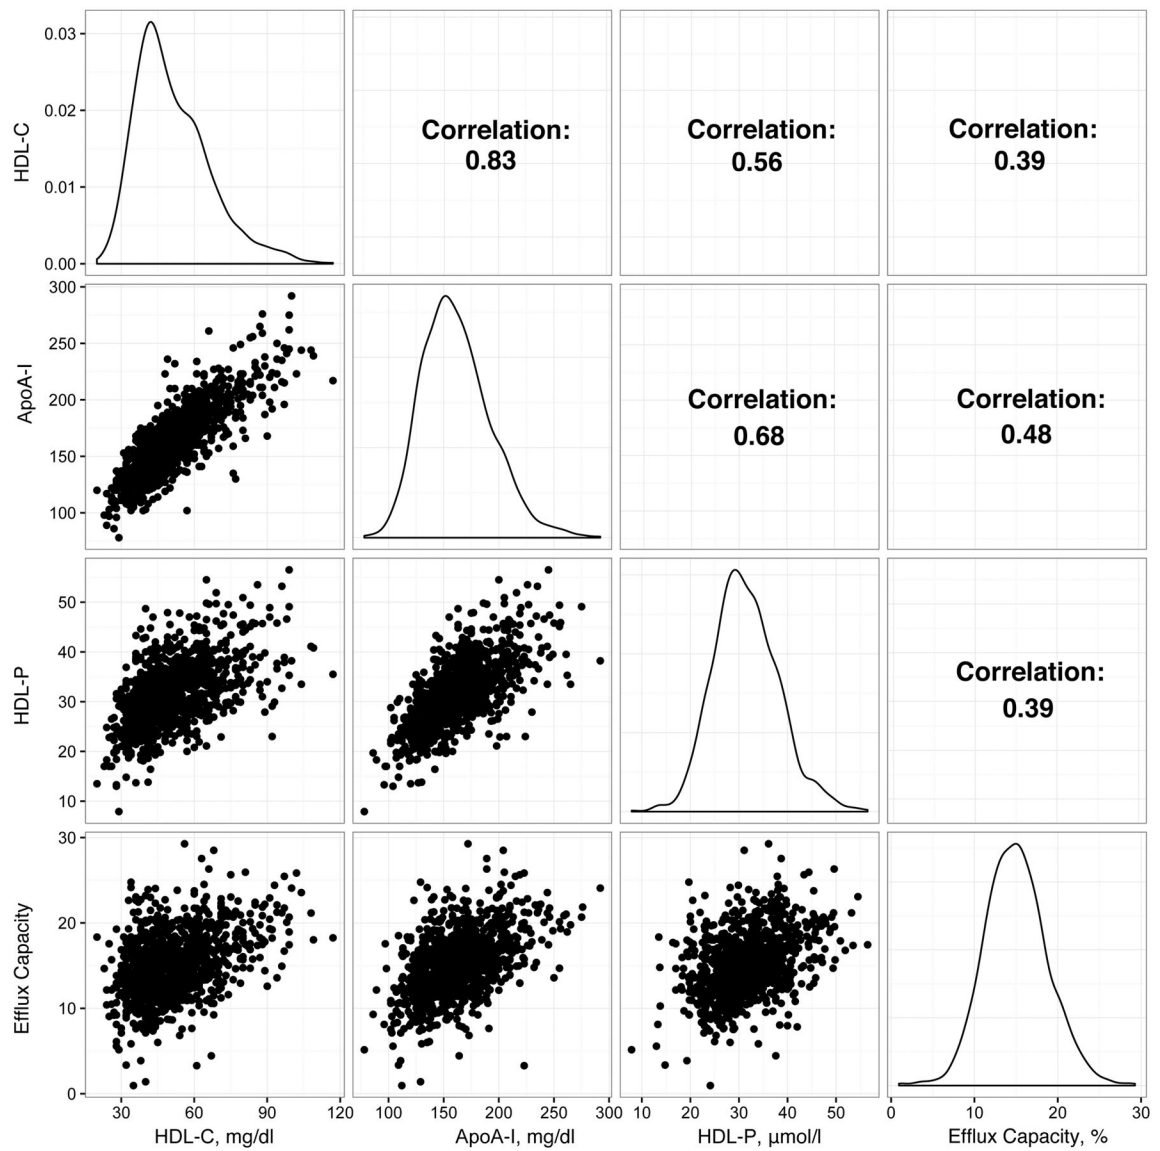

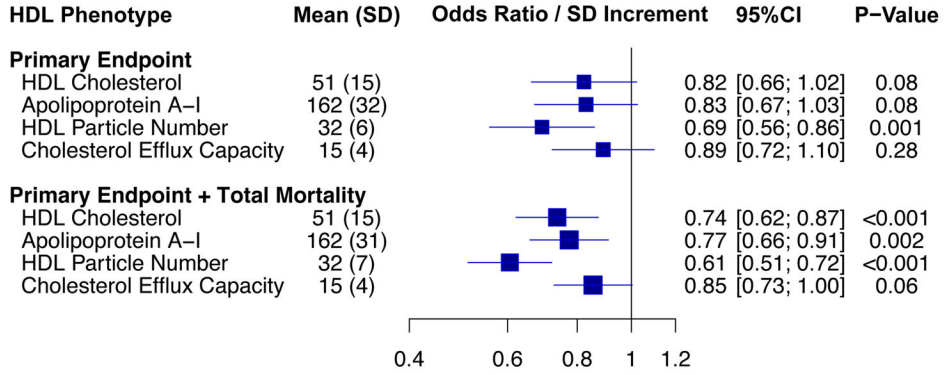

Figure 1. Spearman correlations between HDL-related biomarkers. Distributions for each biomarker and pairwise Spearman correlation coefficients and scatterplots are displayed. HDL-C – high-density lipoprotein cholesterol; ApoAI – apolipoprotein A-I; HDLP – high-density lipoprotein particle number; Efflux capacity – cholesterol efflux capacity.

A. Baseline Biomarkers

B. On-statin Biomarkers

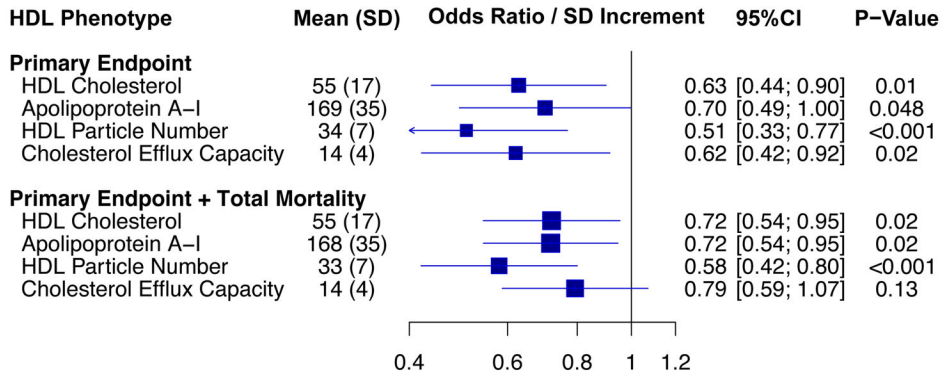

Figure 2.

Associations for baseline or on-statin HDL-related biomarkers and incident events. Odds ratios for baseline (A) and on-statin (B) HDL-related biomarkers are reported per standard deviation (SD) increment based on a conditional logistic regression analysis adjusted for matched design as well as for the following risk factors and biomarkers: age, race, treatment group, smoking status, systolic blood pressure, body-mass index, fasting glucose, LDL cholesterol level, log-transformed triglycerides, and family history of premature coronary artery disease. Models analyzing on-statin biomarkers incorporated on-treatment values for LDL cholesterol and log-transformed triglycerides.

Table 1

Baseline Characteristics

	Primary Endpoint Controls (N=314)	Primary Endpoint Cases (N=314)	Primary Endpoint + Total Mortality Controls (N = 525)	Primary Endpoint + Total Mortality Cases (N=525)

Apolipoprotein A-I	161(140–186)	155(137.8–175)*	162(141–183)	156(139.5–177)*
HDL Particle Number, μ mol/l	32.8(27.9–37.6)	30.4(26.6–35.2)*	32.5(27.9–36.9)	29.8(26–34.6)*
Cholesterol Efflux Capacity, %	15.4(12.8–18)	15.1(12.8–17.6)	15(12.5–17.6)	14.8(12.4–17.1)

Values represent n(%) or median (25–75%). FH – Family History; CHD – Coronary Heart Disease; hsCRP – high-sensitivity C-Reactive Protein; Lp-PLA2 – lipoprotein-associated phospholipase A2; LDL – low-density lipoprotein; HDL – high-density lipoprotein.

* indicates Chi-square or Wilcoxon rank-sum test p-value < 0.05

[†] Family history of premature coronary disease was defined as diagnosis of the disease in a male first-degree relative before the age of 55 y or in a female first-degree relative before the age of 65 y.

Table 2

Baseline Cholesterol Efflux Capacity According to Clinical Subgroups

	N	Median (25th – 75th%)	P Value
Sex			
Male	752	14.5(12.2–16.9)	<.0001
Female	298	15.7(13.4–18.2)	
Treatment Group			
Placebo	600	14.8(12.4–17)	0.11
Rosuvastatin	450	15.2(12.4–17.8)	
Current Smoker			
No	872	14.9(12.5–17.4)	0.75
Yes	177	14.9(12.4–17.1)	
FH of Premature CHD*			
No	900	14.9(12.4–17.3)	0.42
Yes	149	15.3(12.8–17.4)	
Metabolic Syndrome			
No	650	14.9(12.6–17.4)	0.28
Yes	392	14.8(12.3–17)	

P values derived from Wilcoxon rank-sum test.

* Family history of premature coronary disease was defined as diagnosis of the disease in a male first-degree relative before the age of 55 y or in a female first-degree relative before the age of 65 y.

Table 3
Association between Baseline Cholesterol Efflux Capacity and Incident Cardiovascular Events

	Tertile One	Tertile Two	Tertile Three	P-Trend	OR/SD Increment
Primary Endpoint					
Range, %	1.0 – 13.6	13.6 – 16.8	16.9 – 28.5		
N (N Cases/N Controls)	210 (105/105)	209 (111/98)	209 (98/111)		628 (314/314)
Model One					
Odds Ratio (95%CI)	Reference	1.12 (0.75 – 1.67)	0.84 (0.55 – 1.27)	0.43	0.94 (0.79 – 1.13)
P-value		0.59	0.41		0.52
Model Two					
Odds Ratio (95%CI)	Reference	1.08 (0.70 – 1.67)	0.75 (0.47 – 1.21)	0.26	0.89 (0.72 – 1.1)
P-value		0.73	0.24		0.28
Primary Endpoint Plus Total Mortality					
Range, %	1.0 – 13.4	13.4 – 16.5	16.5 – 29.3		
N (N Cases/N Controls)	350 (182/168)	350 (180/170)	350 (163/187)		1050 (525/525)
Model One					
Odds Ratio (95%CI)	Reference	0.95 (0.69 – 1.30)	0.77 (0.55 – 1.06)	0.11	0.90 (0.78 – 1.03)
P-value		0.75	0.11		0.12
Model Two					
Odds Ratio (95%CI)	Reference	0.98 (0.7 – 1.39)	0.69 (0.48 – 1.01)	0.06	0.85 (0.73 – 1.00)
P-value		0.92	0.05		0.06

Model One: Conditional logistic regression odds ratio adjusted for age and treatment group. Model Two: Odds ratio adjusted for age, treatment group, race, smoking status, systolic blood pressure, body-mass index, fasting glucose, baseline low-density lipoprotein cholesterol level, baseline log-transformed triglyceride level, and family history of premature coronary artery disease. OR – Odds Ratio. P-trend – P-value for linear trend across tertiles.

Table 4

Impact of Randomized Rosuvastatin Therapy Versus Placebo on HDL-Related Biomarkers Levels

HDL Phenotype	Placebo	Rosuvastatin	P Value vs. Placebo
HDL Cholesterol			
N	481	369	
Mean at baseline, mg/dl	51.0	51.6	
Mean at 12mo, mg/dl	51.8	54.8	
Percent Change (95%CI)	2.6 (1.2 – 2.4)	7.7 (5.8 – 9.5)	<0.0001
P Value vs. Baseline	0.0003	<0.0001	
Apolipoprotein A-I			
N	476	364	
Mean at baseline, mg/dl	161.5	162.6	
Mean at 12mo, mg/dl	163.4	168.2	
Percent Change (95%CI)	1.9 (0.7 – 3.1)	4.3 (2.7 – 6.0)	0.02
P Value vs. Baseline	0.002	<0.0001	
HDL Particle Number			
N	428	312	
Mean at baseline, μ mol/l	31.5	31.4	
Mean at 12mo, μ mol/l	31.4	33.2	
Percent Change (95%CI)	-1.6 (-3.1 – 0.1)	5.2 (3.1–7.3)	<.0001
P Value vs. Baseline	0.04	<0.0001	
Cholesterol Efflux Capacity			
N	369	248	
Mean at baseline, %	14.9	15.2	
Mean at 12mo, %	14.1	13.8	
Percent Change (95%CI)	-3.3 (-7.9 – 1.2)	-1.5 (-13.3 – 10.2)	0.78
P Value vs. Baseline	0.15	0.80	

Mean percent changes from baseline to twelve-months of therapy calculated. P values versus baseline and placebo determined via one-sample and two-sample t tests respectively.

Table 5
Association between On-Statins Cholesterol Efflux Capacity and Incident Cardiovascular Events

	Tertile One	Tertile Two	Tertile Three	P-Trend	OR/SD Increment
Primary Endpoint					
Range, %	5.85–11.87	11.88–15.54	15.55–25.31		
N (N Cases/N Controls)	60 (31/29)	59 (29/30)	59 (20/39)		
Model One					
Odds Ratio (95%CI)	Reference	0.92 (0.45 – 1.90)	0.36 (0.16 – 0.84)	0.02	0.66 (0.47 – 0.94)
P-value		0.82	0.02		0.02
Model Two					
Odds Ratio (95%CI)	Reference	0.79 (0.35 – 1.77)	0.31 (0.12 – 0.75)	0.01	0.62 (0.42 – 0.92)
P-value		0.57	0.01		0.02
Primary Endpoint + Total Mortality					
Range, %	5.17–11.5	11.6–15.4	15.5–25.3		
N (N Cases/N Controls)	83 (39/44)	82 (39/43)	83 (34/49)		
Model One					
Odds Ratio (95%CI)	Reference	1.04 (0.56 – 1.92)	0.64 (0.33 – 1.23)	0.20	0.86 (0.66 – 1.13)
P-value		0.90	0.18		0.27
Model Two					
Odds Ratio (95%CI)	Reference	0.99 (0.5 – 1.94)	0.51 (0.25 – 1.04)	0.07	0.79 (0.59 – 1.07)
P-value		0.98	0.07		0.13

Model One: Odds ratio adjusted for age and treatment group. Model Two: Odds ratio adjusted for age, treatment group, race, smoking status, systolic blood pressure, body-mass index, fasting glucose, on-statin low-density lipoprotein cholesterol level, on-statin log-transformed triglyceride level, and family history of premature coronary artery disease. OR – Odds Ratio. P-trend – P-value for linear trend across tertiles.
