The prehistory of wild potato use, leading to its domestication and diversification, has been well-documented in, and confined to, South America. At least 20 tuber-bearing, wild species of *Solanum* are known from North and Central America, yet their importance in ancient diets has never been assessed from the archaeological record. Here, we report the earliest evidence of wild potato use in North America at 10,900–10,100 calendar years (cal) B.P. in the form of well-preserved starch granules extracted from ground stone tools at North Creek Shelter, southern Utah. These granules have been identified as those of *Solanum jamesii* Torr. (Four Corners potato), a tuber-bearing species native to the American Southwest. Identification was based on applying five strictly defined diagnostic characteristics (eccentric hilum, longitudinal fissure, lack of fissure branching, fissure ratio, and maximum granule size) to each of 323 archaeological granules. Of those, nine were definitively assigned to *S. jamesii* based on possession of all characteristics, and another 61 were either likely or possibly *S. jamesii* depending on the number of characteristics they possessed. The oldest granules were found in substratum 4k (10,900–10,100 cal B.P.). Younger deposits, dating to ~6,900 cal B.P., also contained tools with *S. jamesii* granules, indicating at least 4,000 y of intermittent use. Ethnographic and historical accounts extend the period of use to more than 10,000 y. The question then arises as to whether some *S. jamesii* populations could have undergone transport, cultivation, and eventual domestication over such a long period of time.

potato | *Solanum jamesii* | starch granule analysis | tuber use | Colorado Plateau

The discovery of starch granules persisting on ground stone artifacts has established early dates for the dietary use of many wild plant species, including 32,600 calendar years (cal) B.P. for oat (*Avena*) in southern Italy (1); 30,000 cal B.P. for cattail (*Typha*) in central Italy and the Czech Republic (2); 23,000 cal B.P. for barley (*Hordeum*) and wheat (*Triticum*) in Israel (3); and 23,000–19,500 cal B.P. for grasses (Triticeae and Paniceae), beans (*Vigna*), yams (*Dioscorea*), and snakegourd roots (*Trichosanthes*) in China (4). These dates are significant because they are often used to establish the ancestry of domesticated plants that eventually diverged from wild relatives (5–8).

In the case of tuber-forming species of *Solanum*, archaeological tubers found in Casma Valley, Peru, have been directly dated to 7,800 cal B.P. (9, 10). The tubers contained starch granules resembling those of the domesticated *Solanum tuberosum* but may have still represented a wild species (10). Intensive exploitation, perhaps of domesticated strains, took place between 3,400 and 1,600 cal B.P. in the western Titicaca Basin (11).

Herein, we report on starch granules from the wild Four Corners potato, *Solanum jamesii* (Fig. 1), found on ground stone tools in deposits dating between 10,900 and 10,100 cal B.P. at North Creek Shelter (NCS) near Escalante, Utah. This discovery is the earliest documented use of potatoes in North America, an important energy source that has been largely undervalued or even ignored when diet breadth analyses and optimal foraging theory are applied in archaeological studies (12, 13).

Study Site: Archaeological Context

NCS is a deeply stratified site at the base of a south-facing sandstone cliff at an elevation of 1,900 m (37°46.200' N, 111°40.812' W) (Fig. 2). Excavations of NCS occurred between 2004 and 2008, uncovering numerous hearths and pits and abundant stone tools, faunal assemblages, and botanical remains (14). The excavations revealed seven cultural strata, dating from 11,500 to 150 cal B.P. Thirty-five radiocarbon dates were obtained on various materials (bone/collagen, dentin, wood/charcoal, fruits/seeds; Table S1), allowing strata to be further subdivided into 68 substrata, some interpreted as short-term living/use surfaces (14) (Fig. S1 and Table S1).

Among the archaeological materials were 196 ground stone tools (manos and metates, hand and milling stones, respectively) varying in abundance from Paleoarchaic to Late Prehistoric times (10,900–150 cal B.P.) (14). The majority had been manufactured from sandstone (88%) and most (85%) were fragmented (Table S2). Manos were bun-shaped, one- or two-sided, and tended to be complete. The seven complete metates were slabs up to 46 cm in length with one or two smoothly ground basin surfaces (Fig. 3). The ages of these artifacts were established by radiocarbon dating of associated materials from the same substratum. The greatest number of tools occurred in substrata 5t and 5u (9,300–8,500 cal B.P.), suggesting a technological and dietary shift toward intensive use of plant resources that has been observed at about this time in many other locations across arid western North America (15–18).

Results

Extractions of surface and interstitial residues were performed on 101 ground stone tools from strata 4, 5, and 6 and on seven

Significance

Starch granules of *Solanum jamesii* extracted from ground stone tools establish wild potato use as early as 10,900–10,100 calendar years B.P. in southern Utah. This discovery is the earliest documented use of potatoes in North America, an important energy source that has been largely undervalued or even ignored when diet breadth analyses and optimal foraging theory have been applied in archaeological studies. Younger deposits also contained tools with *S. jamesii* granules, indicating at least 4,000 years of intermittent use. Ethnographic and historical accounts from the region extend the period of use to more than 10,000 years. Given this long prehistory and history, the question arises as to whether some *S. jamesii* populations could have undergone transport, cultivation, and eventual domestication over such a long period of time.

Fig. 3. Slab metate (2004.8.2346.1) from substratum 5u and two-sided mano (2004.8.3474.1 and 2004.8.3474.2) from substratum 5t. Both yielded starch granules of *S. jamesii* and dated between 9,300 and 8,500 cal B.P. (NCS collections held at BYU Museum of Peoples and Cultures).

Discussion

Ethnographic accounts of *S. jamesii* use come from Apache, Hopi, Kawaik, Navajo, Southern Paiute, Tewa, Zia, and Zuni groups (22–27). There were various cooking and processing techniques associated with the species. For example, tubers were collected by Apache during late summer, then “boiled, unpeeled and thus eaten. The *S. jamesii* product was sometimes dried, stored, and later ground into flour for making bread” (22, p. 42). *S. jamesii* tubers were also eaten with a pinch of clay to reduce bitterness (24–26).

Tissues of *S. jamesii* are reported to contain the glycoalkaloids solanine, tomatine, and chaconine, which produce the bitterness. These compounds are steroid-based with various sugar moieties attached to hydroxyl groups on the genin portion (28). One report on the glycoalkaloid content of *S. jamesii* found ~100 mg tomatine/g of dried tuber from samples collected at Zuni Pueblo (29). However, collections of tubers from other archaeological

sites in New Mexico and Arizona were found to have significantly lower total glycoalkaloid content (30).

Calvary soldiers on early expeditions into Escalante also consumed wild tubers of *S. jamesii* and remarked that the place had already been named “Potato Valley” by pioneers: “We have found wild potatoes growing from which the valley takes its name” (Captain James Andrus, August 1866, among the first Europeans to enter this region). A soldier’s diary (John S. Adams, Cavalryman, 1866) recorded, “. . . we gathered some wild potatoes which we cooked and ate them; they were somewhat like the cultivated potato, but smaller” (31). Settlers and their descendants also consumed this potato from the 1870s through the Great Depression of the 1930s and are even now grown in a few backyard gardens.

S. jamesii is known to be highly nutritious, having twice the protein, zinc, and manganese and three times the calcium and iron content as *S. tuberosum* (32). Under optimal growing conditions in a greenhouse, a single “mother” tuber produced 125 progeny tubers during a 6-mo growing season. In the field, tubers do not produce shoots until the onset of summer rain, usually in July, but carbon allocation to forming progeny tubers begins as soon as leaves are aboveground. Summer drought and autumn frost cause immediate senescence of shoots. Tubers, however, can persist underground for at least 8 y (33), achieving high densities and yielding at least 1.7 kg of starchy food per 10 m² of habitat area (32). Thus, a summer-active and highly productive herbaceous perennial would have provided a reliable, yearlong source of carbohydrate and minerals that significantly improved dietary quality.

Evidence for the processing of starch-rich tubers has implications with respect to the ecology of human diets and optimal foraging theory. Calculations of dietary species richness and evenness, used to define the energetics of food choices, have traditionally been based on faunal evidence. When macro- and microbotanical evidence are added to the calculations, we are able to achieve a fuller picture of dietary change through time (34). Tubers and other USOs rank just below small- and large-bodied animals (35, 36), therefore energetic gains would be greater than those obtained from small seeds alone. Adding *S. jamesii* to the tally of dietary species richness at NCS would accentuate a shift toward broader diets, especially during the middle Holocene (34). Similar to pine nuts and perhaps acorns, *S. jamesii* would disproportionately mitigate for the loss of higher ranked resources. However, unlike pine nuts and acorns, these perennial tubers would not be susceptible to reproductive failure during the increasing aridity and changing ecosystem composition of the Holocene.

Five small and isolated populations of *S. jamesii* are known from the Escalante Valley, including one only 150 m from NCS (34, 37) (Fig. 2). The next closest population is 150 km to the east in the

Table 1. Summary of starch granules extracted from ground stone tools excavated at North Creek Shelter

*Measurements based on a single grain.

Definitive assignment of nine granules to *S. jamesii* based upon the possession of five diagnostic characteristics. Another 61 granules were likely or possibly *S. jamesii* based upon possession of fewer characteristics (Figs. S3–S5 and Table S3). Fissure ratio calculated from the width of the longitudinal fissure (w_f) and width of the grain (w_g). Mean lengths are from log-transformed data.

Fig. 4. Starch granules of *S. jamesii*. (Upper) Modern reference material from Escalante, Utah. (Lower) Archaeological granules from a ground stone tool (2004.8.3607.2) in substratum 5t (9,300 cal B.P.).

vicinity of Newspaper Rock, another well-known archeological site in southern Utah. At both locations, the species occupies woodlands of pinyon, oak, and cottonwood that did not become established until the mid-Holocene (38). It is likely, therefore, that during the late Pleistocene and early Holocene, when climatic conditions were cooler and the vegetation surrounding NCS was dominated by spruce-fir forest (34), *S. jamesii* was confined to warmer, lower elevation regions of the southwest where monsoonal climates persisted (39). Two other tuber-producing species (*S. fendleri* A. Gray ex Torr. and *S. cardiophyllum* Lindl.) are also restricted to warm, subtropical climates much farther south (40, 41) that would not have been present in the Escalante/Colorado Plateau region during the late Pleistocene and early Holocene. The confinement of tuber-bearing *Solanum* species in North America to warm, monsoonal climates suggests a physiological constraint on distribution that might only be overcome by human transport into favorable microsites at higher latitudes during ancient times. The long prehistory of *S. jamesii* in North America raises the question of whether its populations in the Four Corners region could have undergone transport, cultivation, and eventual domestication.

Materials and Methods

Starch Granule Extraction. Starch granules were extracted from ground stone tools by using three different treatment methods (19). Each residue sample was sieved by using a 125- μ m mesh Endecott sieve (to remove material >125 μ m). Water plus sieved sample (<125 μ m) was transferred to a 50-mL Falcon tube. Samples were centrifuged for 3 min at 2,720 \times *g*. The supernatant was discarded, and the resuspended sample was transferred to a 15-mL centrifuge tube.

A heavy liquid separation technique was used to isolate any starch in the archaeological sample. Sodium polytungstate (Specific Gravity 2.35) was added to the sample pellet in each tube, resuspended with a vortex mixer,

and centrifuged for 15 min at 300 \times *g*. The suspended fraction (with starch if present) was decanted into another set of labeled centrifuge tubes. Two more rinses (addition of DH_2O and centrifugation, 3 min at 2,720 \times *g*) were undertaken to remove any residual heavy liquid. Acetone was added to each, spun, and allowed to dry overnight.

The pellets were resuspended in a few drops of a 50% glycerol and 50% DH_2O solution, and the sample was mounted on a glass slide. Total slide scans were completed by using a Zeiss Axioskop II transmitting, brightfield microscope fitted with polarizing filters and Nomarski optics. A Zeiss HRC digital camera and Zeiss Axiovision and Zen software were used for image capture and archiving (all manufactured by Zeiss International).

Starch Granule Identification. Our approach to identifying archaeological starch granules with eccentric hila began with an ethnographic inventory of all native food plants significant to Utah's southern Paiute people, inhabitants of the Basin-Plateau region (42) (Table S4). Of these 65 plant taxa, those belonging to only two plant families (Solanaceae and Liliaceae) have starch granules with pronounced eccentric hila similar to those of *S. jamesii* (21). We were then able to develop a set of strict, statistically defined diagnostic characteristics so that archaeological granules from many species could be sorted for purposes of identification. Using reference materials from three populations of *S. jamesii* (21), those characteristics included (i) possession of an eccentric hilum, (ii) the presence of a longitudinal fissure, (iii) the absence of fissure branching, (iv) a ratio of fissure width to granule width in the range of 0.21–0.28 (mean ratio \pm 99% CI), and (v) mean maximum granule length (top 20% of granules possessing characteristics 1–3) greater than 34.88 μ m (mean minus the 99% CI).

The utility of starch granules in archaeobotanical studies depends heavily on achieving high levels of confidence during the process of identification (43, 44). Assignment of archaeological granules to any taxonomic level is facilitated by larger sample sizes, a greater number of diagnostic characteristics, the use of metrics for establishing objective criteria, and comparisons with modern reference material (21). Statistical analyses can then be used to characterize interpopulation and interspecific variation and the effects of selection under domestication. Confidence in our identifications has been elevated by (i) the use of substantial archaeological starch assemblages, (ii) statistically robust reference sample sizes systematically examined for variation within and between populations and (iii) the derivation of at least five measurable or strictly defined diagnostic characteristics. Having a smaller subset of potential food plants, in this case possessing eccentric hila, limited the number of comparisons between archaeological and reference materials.

Background Starch Concentrations from Surrounding Sediments. Sediment samples were collected from the east and west walls of the NCS excavations during 2006 and 2007 (14) and included substrata 5a, 5f, 5q, 5s, 5t, 6a, and 6d. No sediment samples were collected from substrata 4k, 5r, or 5u. Sediment samples were processed for starch to establish background concentrations. All were weighed and transferred to 50-mL Falcon tubes. Deflocculation of clays was facilitated by the addition of Calgon (sodium hexametaphosphate) and gentle agitation for several hours.

To directly compare starch granule counts, sediment samples and a subsample of residue samples (19) were normalized by weight. One gram of material from seven sediment samples was processed according to standard protocols (45). Weights were determined for residue samples ($n = 34$) by recording the dry weight of stones before and after sonication. All residue weights were less than 0.1 g, about one-tenth of the sediment weights. Because there was 10 times more sediment than residue in any one sample, the probability of detecting background levels of starch granules was increased.

Contamination Sources. Starch contamination can originate in soils, air currents, and on laboratory and human surfaces (46–49), so precautions were taken to minimize contamination of the samples. In this study, sources of contamination were linked to slide preparation rather than laboratory processing. For example, new sheets of Whatman's lens papers and human fingertips could be sources of starch contaminants. Fresh pairs of powder-free laboratory gloves, new microscope slides and coverslips, DH_2O , and bottled glycerol did not, however, contribute detectable amounts of starch granules. We also tested the plastic and paper bags that held the ground stone tools in collections, and the paper labels with accession numbers, none of which were detectable sources of contamination.

ACKNOWLEDGMENTS. Processing for starch residues was conducted in Dr. Judith Field's laboratory at University of New South Wales. Nomarski images (in supporting figures) were taken with Dr. Field's Zeiss microscope.

All other imaging was conducted either at University of Washington or the Archaeobotany Lab at the Natural History Museum of Utah. Joel Janetski generously provided data on archaeological material and chronology from North Creek Shelter. Paul Stavast [Brigham Young University (BYU) Museum of Peoples and Cultures] gave us access to the collections. We thank our friends and colleagues, John Bamberg, Alfonso del Rio, Nicole Herzog, David Kinder, and David Rhode, for thoughtful conversations on starch granule analysis and potato biology; Don Grayson, Joel Janetski, and Benjamin Pavlik

for reading an earlier version of the manuscript and whose comments and suggestions improved our paper; DeLane Griffin, Joette-Marie Rex, David Delthony, and Drew Parkin of Escalante, Utah, for their hospitality and enthusiastic support; and to the native peoples of the greater Four Corners region, the original innovators and stewards of *S. jamesii*. Funding for this research was provided by National Science Foundation Doctoral Dissertation Improvement Grant 1262835 and a Funding Incentive Seed Grant from the University of Utah.
