Abstract

Objective—To investigate gender-specific trajectories in well-being among older people with coronary heart disease (CHD) and to compare them to those of healthy people.

Method—4,496 participants from the first three waves of the English Longitudinal Study of Ageing (2002/03-2006/07). We measured well-being using quality of life (CASP-19) and depressive caseness (3 or more symptoms on the CESD-8).

Results—After adjustment, at 2 and 4 years follow-up women had 3 points higher quality of life than men (p<0.001). When looking at each quality of life's domain we found that women reported higher scores of Autonomy compared to men. The gender difference in the probability of having depressive caseness reduced to 7 percentage points at 4-year follow-up from 13 percentage points in the previous occasions. Men's quality of life declined progressively over-time by 3 points (p<0.001) (equivalent to the effect of having diabetes) but no changes in prevalence of depressive caseness were found. Women's quality of life only declined after 4-year follow-up by less than 2 points (p<0.001), while in the same period their probability of reporting depressive caseness reduced by 6 percentage points (p<0.001).

Page 2

Conclusions—Women had better quality of life than men in the two and four years following a CHD event, and were not more likely than men to report depressive caseness in the long term. Men's quality of life deteriorated progressively over time, among women it did not deteriorate in the first two years following a CHD event; women had a long-term improvement in depressive caseness.

Keywords

depressive caseness; quality of life; CHD; trajectories

INTRODUCTION

Recent trends indicate that the death rate from coronary heart disease (CHD) reduced by at least two fifths between 2000 and 2010 for men and women aged 55 to 64 in the UK (British Heart Foundation, 2010). Concurrent with the substantial reduction in deaths from CHD, there has been a growing recognition of the importance of outcomes other than survival following CHD, such as well-being. Reduced quality of life and increased risk of depression are common following CHD (Kristofferzon et al., 2005; Norris et al., 2007) and are associated with increased mortality (Lesperance et al., 1996; 2000; Ziegelstein et al., 2000; Bogg et al., 2000; Ferketich et al., 2000; Bush et al., 2001; Carney et al., 2003; Lane et al.; 2005; Parashar et al., 1996), with poor adherence to recommended behaviours and lifestyle changes after the cardiac event (Ziegelstein et al., 2000; 2001)and with an increased risk of readmission because of cardiac complications (Lauzon et al., 2003).

Results from studies exploring longitudinal changes in well-being among men and women hospitalized after CHD reported that women had significantly lower health-related quality of life than men (Norris et al., 2007; Bogg et al., 2000; Westin et al., 1999; Brink et al., 2005) and were more likely to be depressed (Norris et al., 2007) one year post-CHD. However, other studies reported contrasting findings, with no difference between men and women in their prevalence of depression post-CHD (Brink et al., 2005; Wiklund et al., 1993). Results from a community study with a five year follow-up showed that women had a high initial risk for depression with a significant decrease after two years, while the risk for depression for men was only increased in the two to five years after myocardial infarction (Bjerkeset et al., 2005).

Despite the increasing interest in the well-being of people with CHD (Norris et al., 2007, Norris et al., 2007; Bogg et al., 2000; Westin et al., 1999; Brink et al., 2005; Wiklund et al., 1993; Bjerkeset et al., 2005), results from the majority of previous studies have mainly been based on small samples with short follow-up periods (Norris et al., 2007,7,Bogg et al., 2000; Westin et al., 1999; Brink et al., 2005; Wiklund et al., 1993). Research has typically focused exclusively on people with CHD, so direct comparisons with a population free from CHD and other major diseases on well-being have not been possible. Therefore, questions concerning long-term outcome, gender differences, and the role of explaining factors still remain unanswered. Moreover, most of the studies have measured quality of life using a health-related measure such as the short-form-36, which may not be optimal as these measures are based on proxies (such as health) "which draw on a set of normative

assumptions about what a particular condition implies for a person's quality of life without necessarily taking close account of a person's current life experience" (Wiggins et al., 2008). A recent avenue of research looks at positive, rather than negative functioning and this is particularly interesting given that health life expectancy has been improving. Given this interest, an alternative measure of quality of life has been specifically developed for old age, called CASP (Hyde et al., 2003), comprising four domains ('control', 'autonomy', 'pleasure' and 'self-realization'). CASP has been based on theories of need satisfaction (Doyal and Gough, 1991), which assume that quality of life at older ages is conceptualized as the degree to which human needs are satisfied in the above mentioned four domains (Hyde et al., 2003). This measure differs from health-related measures by focusing on positive aspects of quality of life and by being independent of health and other factors that

Using a large population-based sample of older adults living in England, the aims of our study are to explore gender-specific changes in well-being over a six year period among people with CHD and to compared them with a group of individuals free from CHD and other major conditions. In line with current recommendations to distinguish between different aspects of well-being (Dolan et al., 2011; Kahneman et al., 2006) we use quality of life, and depressive caseness.

might influence it (Hyde et al., 2003; Wiggins et al., 2008).

METHODS

Study population

We analysed data from the first three waves (2002-2003 to 2006-2007) of the English Longitudinal Study of Ageing (ELSA) (Steptoe et al., 2012), a panel study where the same individuals are re-interviewed every two years. The ELSA sample was designed to represent people aged 50 and over, living in private households in England. The original sample size was 11,391 at wave 1 (2002-03) (individual response rate of 67%). The analytical sample of this study consists of 4,996 participants with a CHD event occurring (n=895 18%) in the two years preceding the baseline interview (2002-03) and of healthy participants without known longstanding conditions (n=3,601) at baseline. A detailed explanation of the selection of the CHD and healthy participants is given in the next section. Data were collected through face-to-face interviews and self-completion questionnaires. Ethical approval for the ELSA study was provided by the local Ethics Committee and patients or their representatives gave informed consent.

Measures

Well-being—We measured quality of life using the CASP-19 (Hyde et al., 2003) selfcompletion questionnaire. CASP-19 contains 19 items covering four conceptual domains of individual needs that are particularly relevant in later life: Control, Autonomy, Selfrealization and Pleasure. The instrument has four items for the control domain and five for each of the others. Each item is assessed on a four-point Likert scale. The resulting scale scores of Control (range 0 to 12, mean 8.6 s.d 2.5), Autonomy (range 1 to 15, mean 10.8 s.d. 2.6), Self-realization (range 0 to 15, mean 10.6 s.d. 3.1) and Pleasure (range 0 to 15, mean 13.5 s.d. 2.1) are summed to form an index which ranges from 0 to 57 with higher scores

indicating better quality of life (sample specific Cronbach's alpha=0.78). The psychometric properties of CASP-19 are fully described elsewhere (Hyde et al., 2003; Wiggins et al., 2008). In terms of size of effects, a reduction of around 7 quality of life points is associated with having a limiting long-standing illness compared to those without (Netuveli et al., 2006).

We used the eight-item version of the Centre for Epidemiologic Study Depression scale (CESD-8) administered in the face-to-face interview to measure depressive symptoms (Radloff, 1977). The questions asked the degree to which the respondent had experienced (or not) depressive symptoms such as restless sleep and being unhappy, over the past month. The total score, which ranges from 0 to 8, was dichotomized with score 3 to indicate depression caseness, in line with previous studies that have used this abridged version of the scale (Steffick, 2000; Chou, 2007; Blane et al., 2008; Rice et al., 2009). Caseness does not here signify diagnosed depression. The dichotomy was used in preference to a continuous scale because of the skewed distribution of number of symptoms.

Coronary Heart Disease—Our main exposure was experience of angina and/or a myocardial infarction (henceforth referred to as coronary heart diseases CHD) during the two years prior to baseline. Exposure was identified from the face-to-face interview in which participants were asked whether a doctor had ever told them that they suffered from angina or heart attack and, if so, whether they had angina symptoms or myocardial infarction in the past two years. We compared people with CHD with a reference population of individuals that at baseline had never been diagnosed with CHD, stroke, diabetes, hypertension, pulmonary disease, Alzheimer, Parkinson's, cancer and did not report any limiting longstanding illness (referred to Healthy group). The CHD and Healthy groups include people who might experience CHD and other chronic diseases after baseline.

Covariates—Covariates considered in this study include: gender, age, cohabiting status (0"cohabiting with a partner (married or not)" 1"not cohabiting with a partner"), employment status (three categories, paid employment, completely retired and other), educational attainment (0"yes" 1"no"), quintile of non-pension wealth, smoking status (0"never smoked and ex-smoker" 1"current smoker"), frequency of alcohol consumption (0"less than three times a week" 1"three times a week and more"), physical activity (0"physically active" 1"inactive") whether or not often troubled with pain, one or more limitation with activities of daily living (ADLs), score of positive support (Stafford et al., 2011) received from spouse, children, other relatives and friends(continuous variable with higher scores indicating greater positive support), and number of close friends (continuous variable). These time-varying factors were selected as relevant to the well-being outcomes included in the analyses.

Statistical Analysis

We used random intercepts models (Goldstein, 2003) to examine changes in well-being over time. First, we estimated a linear random intercepts model for quality of life using the index score obtained from the sum of the scores of each domains, Control, Autonomy, Selfrealisation and Pleasure. We then estimated linear random intercepts models for each of the

four domains in order to explore whether different trajectories for the four distinct domains emerge. Lastly a logit random intercepts model was estimated for depressive caseness. The models included an interaction term between gender and time in order to assess genderspecific changes in the outcomes over time. The models were run separately for the CHD and Healthy groups. From the logit random intercepts model, average predicted probabilities were estimated and presented graphically, in the text they were referred to as percentages (probabilities multiplied by 100).

To handle missing data due to loss to follow-up and item non-response we used a multiple imputation technique suitable for longitudinal data: the recently proposed two-fold fully conditional specification (Nevalainen et al., 2009). We created five imputed data sets and we combined the results estimates according to Rubin's rule (1996). When using multiple imputation methods it is recommended to include auxiliary variables predictive of missingness in the imputation model (Sterne et al., 2009)even if they are not of interest in the substantive model. We therefore added five variables (measured at baseline) which were found to be predictive of non-response (Scholes et al., 2008) to the imputation model, these variables are: year of HSE interview, Government Office Region, housing tenure, number of people in the household and ethnicity. Statistical significance was assessed with a p-value 0.01, whereas a p-value up to 0.05 was considered as borderline significant. All analyses were run in Stata version 11.1.

RESULTS

Table 1 shows baseline characteristics of participants by disease status and gender. Men and women with CHD were on average older and had lower quality of life than men and women from the Healthy group. The prevalence of those reporting depressive caseness was higher in men and women with CHD compared to people in the Healthy group. The prevalence of being retired, in low education, with poor wealth, physically inactive, drinking alcohol on three or more days a week, often troubled with pain and with one or more limitations with ADLs was higher in men and women with CHD compared with men and women from the Healthy group. Women with CHD were also more likely than women from the Healthy group not to be cohabiting and less likely to be in the richest quintiles of wealth (5th and 4th). Men with CHD received on average lower positive social support than men from the Healthy group.

Changes in quality of life

Table 2 reports the changes over time in quality of life by gender among people with CHD and the Healthy group obtained using random intercepts models (imputed data), results are presented fully adjusted. Figure 1 shows graphically the results reported in Table 2. Among men with CHD the adjusted mean quality of life score at baseline was 47.4, which decreased to 46.5 at two year follow-up (borderline significant p=0.034) and to 44.6 at four year follow-up (p<0.001). The adjusted mean quality of life score at baseline for women with CHD was 48.2, which remained stable at two year follow-up (48.4), and then decreased to 46.5 at four year follow-up (p<0.001). At two year follow-up and at four year follow-up (borderline significant people) at the people of the peop

women had significantly higher quality of life than men (2004-05:coeff 1.82 95%CI 0.83-2.81, p<0.001; 2006-07: coeff 1.82 95%CI 0.83-2.80 p<0.001) (Table 2 and Figure 1).

Among men and women in the Healthy group, quality of life decreased substantially over time (Table 2 and Figure 1). Men and women in the Healthy group had similar changes in quality of life over time and only at two year follow-up was the quality of life of women slightly higher than that of men (2004-05: coeff 0.49 95% CI 0.36-0.93 p=0.016);the difference was borderline significant and not clinically important.

The adjusted quality of life of men with CHD was over 1.4 points lower than the quality of life of men from the Healthy group, at each measurement occasion. The adjusted quality of life of women with CHD was 1.1 points lower than the quality of life of women from the Healthy group at baseline, while at two and four year follow-ups it was almost the same.

Table 3 shows changes over time in each domain of quality of life by gender among people with CHD and the Healthy group. To simplify interpretation results are presented as fully adjusted mean estimated using random intercepts models (imputed data). For each domain of quality of life, the score decreases over time in men and women from CHD group and from the Healthy group. The Autonomy domain is the aspect of quality of life for which men and women in the CHD group reported gender differences, while for the other domains the results were not statistically significant. Among people in the healthy group, only at wave 2 (2004-05) women reported higher scores of Autonomy compared to men, while on all other occasions and for all other domains of quality of life they reported similar results.

Changes in depressive caseness

Changes in prevalence of depressive caseness estimated using adjusted random intercepts models are presented in Table 4.Women with CHD had higher odds of depressive caseness than men at baseline and two-year follow-up, independent of covariates adjustment (2002-03: OR 1.99 95% CI 1.24-3.19 p<0.01; 2004-05: OR 1.76 95% CI 1.08-2.86 p=0.023). The odds of depressive caseness were constant over time among men with CHD, while women with CHD were less likely to report depressive caseness at four year follow-up compared to baseline, however, the difference was borderline significant (OR: 0.63 95% CI 0.40-0.97 p=0.024).

From the models presented in Table 4 we estimated the adjusted predicted probabilities of depressive caseness and presented these results graphically in Figure 2. The probabilities are presented in the text as percentages. The probabilities of depressive caseness were fairly constant over time for men with CHD and men and women from the Healthy group. For women with CHD the prevalence of depressive caseness was constant between baseline and two-year follow-up but was 8 percentage points lower at four year follow-up (2006-07) compared to baseline (p<0.001).At baseline and at two year follow-up women had 13 percentage points higher probability of reporting depressive caseness compared to men (p=0.023), this difference reduced to 7 percentage points at four year follow-up (p=0.517).

After adjusting for covariates, men with CHD had 10 percentage points higher probability of depressive caseness compared with in the Healthy group only at four year follow-up

(p=0.024). Baseline differences in depressive caseness between people with CHD and those in the Healthy group, shown in Table 1, were no longer statistically significant when the model was adjusted for covariates. At each assessment women with CHD had the same probability of reporting 3 or more depressive symptoms as women from the Healthy group after adjustment. Gender differences in depressive caseness were found at each assessment in the Healthy group.

DISCUSSION

In this large population-based study of older people living in England we found genderspecific changes over time for quality of life and depressive caseness among people with CHD. For men, quality of life decreased progressively over time by approximately three points (which in the whole ELSA sample is equivalent to the effect of having diabetes), while for women it remained stable in the first two years, only declining at four year followup by less than two points. We showed that at two year follow-up and four year follow-up women had on average three points higher quality of life than men. It was found that the domain of quality of life for which men and women report differences is Autonomy.

Changes in prevalence of 3 or more depressive symptoms also differed according to gender. The probability of this depressive caseness did not change significantly over time for men. For women the prevalence at two year follow-up was the same as at baseline, while at four year follow-up prevalence had reduced below the baseline level. We found gender differences in depressive caseness independent of covariates at baseline and at two year follow-up but not at four year follow-up.

In the Healthy group men and women reported similar trajectories of quality of life and depressive caseness. Women were more likely than men to have depressive caseness at each assessment; whereas quality of life only differed by gender at two year follow-up and was higher for women than men..

After adjustment we found that men with CHD had lower quality of life than men from the Healthy group at each follow-up, while their probability of depressive caseness was higher at four year follow-up only. Women with CHD had lower quality of life than women in the Healthy group at baseline but no significant differences were found in depressive caseness at any time.

Our finding of no gender differences in quality of life at baseline is in agreement with two earlier studies of myocardial infarction patients (Kristofferzon et al., 2005; Mendes de Leon et al., 2001). Our study is the first to show that women's quality of life is better than men's quality of life in the two and four years following a CHD event. To our knowledge, this study is also the first to show that women's quality of life does not deteriorate in the first two years following a CHD event, while men's quality of life deteriorated progressively over time.

Our observation that women are more likely than men to report depressive caseness following a CHD event is well-known (Forrester et al., 1992; Mallik et al., 2006) However, this study is the first to show that in unadjusted analyses gender differences are present at

baseline and at two year follow-up but not at four year follow-up. The gender difference in depressive caseness disappeared after adjustment for covariates, implying that it was other characteristics rather than gender per se that led to the observed difference in crude analysis. Only one previous study reported that gender differences in the mental health dimension of health-related quality of life found at one year post-myocardial infarction did not persist once the model was adjusted for demographic, clinical, comorbid and psychosocial covariates (Norris et al., 2007). Our finding of an improvement in depressive caseness in women is somewhat in line with the study of Bjerkeset et al., (2005) which showed that women had a significant decrease in the risk of depressive symptoms (measured using a cut-off of 8 and more symptoms on the Hospital Anxiety and Depression rating Scale) two year post-myocardial infarction.

We found that among people with CHD, depressive caseness was constant over time among men while women reported an improvement. Quality of life decreased in both men and women in the long term, although for women the decrease was less important. It is possible that depressive caseness reflected the immediate psychological reaction to the cardiac event, while the long term decline in quality of life was the consequence of the burdens that the disease placed on the health and socioeconomic status of individuals. A CHD event often involves changes to an individual's lifestyles, therefore recovery from poor quality of life might require a long time, especially in those who as a result of the disease have experienced loss of control and autonomy. Results of this study provided evidence of lower autonomy among men who experienced CHD compared to women. In this sample of older people, the long term decline in quality of life could also be partly a consequence of ageing. This is supported by our finding of a decline over time in quality of life among healthy individuals, and it is consistent with previous studies reporting a trend of worsening quality of life over time especially at older ages (Zaninotto et al., 2009). On the other hand, the improvement in depressive caseness seen in women might reflect a process of adaptation to the disease. It is thought that women may generally have more effective coping strategies for managing stressful life events than men (Hobfoll et al., 1994). In particular, after experiencing myocardial infarction women are more likely than men to adopt problem-focused and emotion-focused coping strategies (Bogg et al., 2000). Learning more about how women cope with CHD may provide lessons that will help men adopt more effective strategies for long-term recovery in their quality of life.

No previous studies have reported a decrease over time in the quality of life of women concomitant with a reduction in the risk of reporting 3 or more depressive symptoms. One possible explanation might be in the relatively long follow-up of our study. Another possible explanation might be that women reported depressive caseness as a consequence of the disease, therefore in the long term they might have adjusted to the CHD event and consequently their mental health improved.

Study strengths and limitations

One of the strengths of this study is the use of a large sample of older people living in private households in England. The study was designed to collect information on topics necessary to understand the economic, social, psychological and health elements of the

ageing process. Some of the advantages of using this data set include adjustment for several important covariates; and the ability to compare the results for the CHD population with those of a Healthy group of people of similar age. This allowed us to determine whether patterns of change over time were specific to CHD, or reflected more general trends in men and women as they grow older.

Another strength of this study is the use of two distinct measures of well-being. By exploring both quality of life and depressive caseness after the CHD event it was possible to untangle aspects of people's well-being never formally identified before. Results from this study highlight the difference between these two aspects of people's well-being and contribute to the current debate on the importance of measuring them separately to develop a broader appreciation of people's lives (Dolan et al., 2011; Kahneman et al., 2006).

The treatment of missing data constitutes a further strength of this analysis. Missing data often occur in epidemiological studies where non-response is a major problem. The development of sophisticated missing data techniques allows researchers to improve the validity of research results (Sterne et al., 2000). We used a technique to impute missing data particularly suitable for repeated measures, the recently developed two-fold fully conditional specification (Nevalainen et al., 2009).

One possible limitation of this analysis is the use of a self-reported measure of CHD. Although an objective measure of CHD would have been preferable, a number of validation studies have demonstrated that self-reported CHD is reasonably accurate when compared with medical records (Lampe et al., 1999; Baumeister et al., 2010). Furthermore, no allowance was made for the severity of cardiac illness. Some people will have more severe CHD than others, but we were unable to take this into account in the analyses. Also, no distinction was made between first and recurrent CHD events, so we implicitly assumed that a recent recurrence was as important as the first onset.

Our measure of depression is not designed to detect depressive illness; therefore we were unable to account for the severity or the chronicity of depression. However, we believe that reporting at least 3 symptoms is valid as a negative indicator of mental health.

Lastly, the changes in quality of life and depressive caseness were analysed according to disease status at baseline. About 3% of people in the Healthy group experienced a CHD event after the baseline interview and 7% developed other diseases (such as diabetes, stroke, pulmonary disease, Alzheimer, Parkinson's and cancer). As a consequence, the healthy controls were not necessarily free of disease at follow-up. The decision not to exclude people that developed a chronic condition at follow-up was made to allow fair comparisons with the group of people with CHD, who at subsequent waves have also experienced a chronic condition and about 12% of them experienced a repeat CHD event might have affected their quality of life and depressive caseness.

CONCLUSIONS

We found that changes over time in quality of life differed from those for depressive caseness after a CHD event. Men's quality of life declined over time and no changes in

depressive caseness were found. Women's quality of life declined slightly only between baseline and four year follow-up, while in the same period their risk of having depressive caseness diminished. In the long term women with CHD reported higher scores of quality of life than men, and when looking at each domain of quality of life it was found that they reported higher scores of Autonomy. No gender differences in depressive caseness were found.

Our findings might inform caregivers that after CHD the mental health of men in terms of depressive caseness does not necessarily deteriorate over time, and the mental health of women could even improve in the long term. On the other hand, men seem to be less able to cope with the disease in the long term with respect to their quality of life and in particular in the Autonomy domain of quality of life. Men's quality of life should be monitored in the years following the event in order to reduce the risk of long term deterioration and to help them to maintain autonomy. Health professionals might advise patients and their immediate relatives on effective strategies for coping with cardiac events in order to help maintain good mental health and quality of life. The findings of this study indicate that the focus of such advice might differ between men and women.

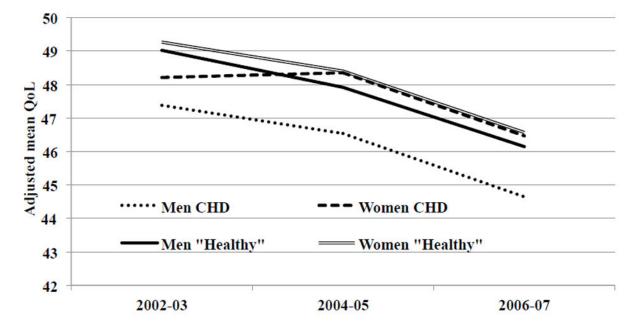

Figure 1.

Trajectories over time of quality of life among people with CHD and the Healthy group, by gender. England 2002-03 to 2006-07

Results adjusted for gender, age, quadratic effect of age, cohabiting status, employment status, educational attainment, wealth, smoking status, alcohol consumption, physical activity, pain, ADLs, depressive caseness, positive support and number of close friends and family. Results based on five imputed data sets.

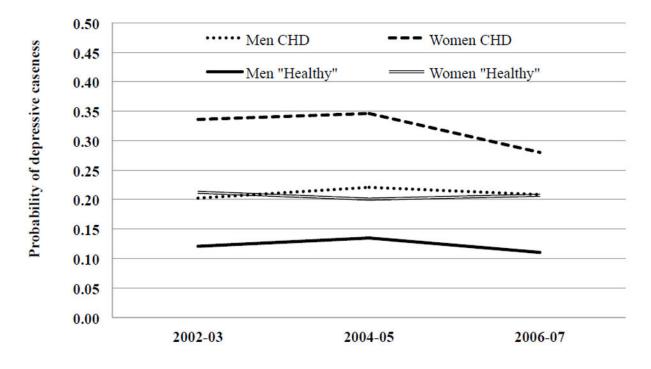

Figure 2.

Predicted probabilities of depressive caseness among people with CHD and the Healthy group, by gender. England 2002-03 to 2006-07

Results adjusted for gender age, cohabiting status, employment status, educational attainment, wealth, smoking status, alcohol consumption, physical activity, pain, ADLs, positive support and number of close friends and family. Results based on five imputed data sets.

Table 1

Baseline characteristics by gender and disease status. England 2002-03

	Men CHD group (n=518)	Men Healthy group ^{<i>a</i>} (n=1,702)		Women CHD group (n=377)	Women Healthy group ^{a} (1,899)	
	Mean (SD)	Mean (SD)	P-value	Mean (SD)	Mean (SD)	P-value
