**ABSTRACT** *Cryptococcus neoformans*, the causative agent of cryptococcosis, is an opportunistic fungal pathogen that kills over 200,000 individuals annually. This yeast may grow freely in body fluids, but it also flourishes within host cells. Despite extensive research on cryptococcal pathogenesis, host genes involved in the initial engulfment of fungi and subsequent stages of infection are woefully understudied. To address this issue, we combined short interfering RNA silencing and a high-throughput imaging assay to identify host regulators that specifically influence cryptococcal uptake. Of 868 phosphatase and kinase genes assayed, we discovered 79 whose silencing significantly affected cryptococcal engulfment. For 25 of these, the effects were fungus specific, as opposed to general alterations in phagocytosis. Four members of this group significantly and specifically altered cryptococcal uptake; one of them encoded CaMK4, a calcium/calmodulin-dependent protein kinase. Pharmacological inhibition of CaMK4 recapitulated the observed defects in phagocytosis. Furthermore, mice deficient in CaMK4 showed increased survival compared to wild-type mice upon infection with *C. neoformans*. This increase in survival correlated with decreased expression of pattern recognition receptors on host phagocytes known to recognize *C. neoformans*. Altogether, we have identified a kinase that is involved in *C. neoformans* internalization by host cells and in host resistance to this deadly infection.

**KEYWORDS** *Cryptococcus neoformans*, fungal pathogenesis, image-based screen

*Cryptococcus neoformans* is a ubiquitous encapsulated fungal pathogen that causes pneumonia and meningitis in immunocompromised individuals. Cryptococcal infection is responsible for significant morbidity and mortality in AIDS patients and is the third most common invasive fungal infection in organ transplant recipients (1, 2), causing an estimated one million cases of meningitis and over 200,000 deaths each year (3–5). Current antifungal therapy is hampered by toxicity, the emergence of drug-resistant organisms, and the inability of the host's immune system to aid in resolution of the disease; treatment is further limited by drug cost and availability in the resource-limited settings where this disease is rampant (6, 7).

Cryptococcosis is primarily an opportunistic infection, highlighting the vital role of host immune responses in control of this infection. Once *C. neoformans* enters the host, the first line of defense it encounters is the innate immune system. Phagocytic cells, including macrophages and dendritic cells (DCs), engulf *C. neoformans* and present antigen to initiate the adaptive immune response.

Fungal internalization by host phagocytes may benefit either the pathogen or the host, depending on microbial virulence factors, host species, host immune status, and the stage of infection. Cryptococci can survive and even proliferate in macrophage phagosomes (8, 9), potentially using these host cells to disseminate. This idea is supported by the reduced *C. neoformans* burden observed in multiple tissues when clodronate liposomes were used to deplete phagocytes in mice before infection (10).

Engulfment by host cells is not always a benefit, however, as internalized fungi may also be destroyed by classically activated phagocytes (11–13).

*C. neoformans* enters host phagocytes via multiple receptor-mediated interactions. Cryptococcal cells may be opsonized by complement deposited on the capsule surface, leading to recognition by host complement receptors. They may also be opsonized by antibody binding, with subsequent recognition by host Fc receptors (14). Finally, the polysaccharide capsule itself may directly interact with macrophage cell surface proteins, including multiple pattern recognition receptors (PRRs) (15). We speculated that additional host factors are important for specific fungal internalization and designed a screen to identify the host genes encoding such proteins.

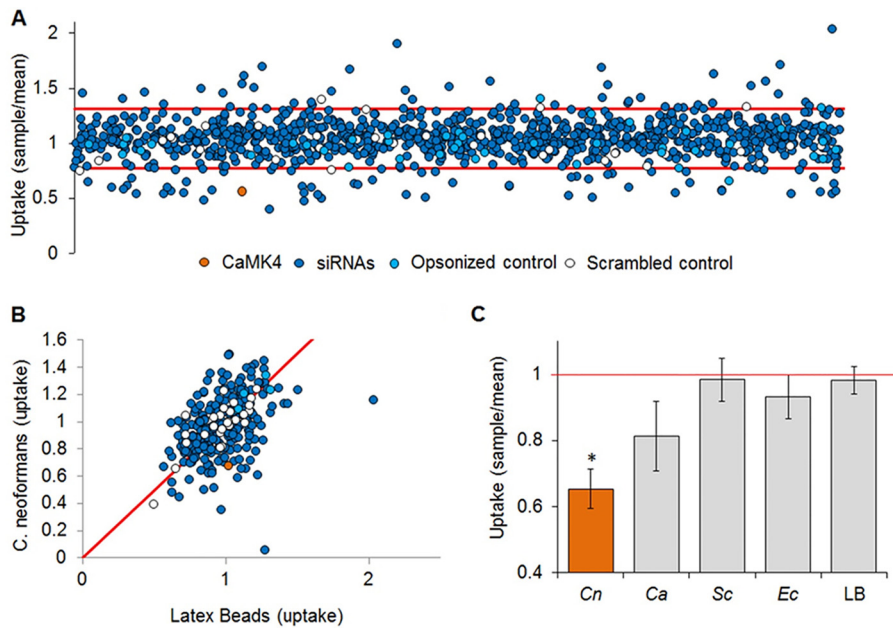

We used an automated imaging-based assay that we previously developed (16) to screen an RNA interference (RNAi) library that targets genes encoding host phosphatases and kinases. We identified four genes whose products are involved in *C. neoformans* internalization by human phagocytes; one of these encodes calcium/calmodulin-dependent protein kinase 4 (CaMK4). Mice lacking CaMK4 survived longer than wild-type (WT) mice after infection with *C. neoformans*, a result that was partly recapitulated by pharmacological inhibition of CaMK4. Immune profiling revealed that the increase in survival time was not due to changes in host cytokine responses or infiltrating immune cells. However, CaMK4 knockout mice infected with *C. neoformans* showed significantly reduced numbers of TLR2, Dectin-1, and CD206-positive phagocytes compared to infected wild-type animals. All three of these pattern recognition receptors have previously been shown to recognize *C. neoformans* (see below). Our studies therefore support a role for this kinase in *C. neoformans* internalization by host cells and in host resistance to this infection.

## RESULTS

**RNAi screening for host factors that influence cryptococcal engulfment.** We hypothesized that host phosphatases and kinases would be among the factors that regulate engulfment of *C. neoformans* by host phagocytes. We took an unbiased approach to identify such proteins and screened human short interfering RNA (siRNA) libraries that target the corresponding sequences. Using a human monocytic cell line, THP-1, as the host cell population, we achieved an average silencing efficiency of over 65% (see Fig. S1 in the supplemental material). Following silencing, the treated THP-1 cells were cultured with stained and serum-opsonized fungi for 1 h and then washed, fixed, and stained for imaging (16). Images were automatically collected and analyzed (see Materials and Methods), and the phagocytic index (fungi internalized per 100 host cells) was determined for each sample.

For our primary screen, we targeted each host gene with a pool of two siRNAs, performing two biological replicates with assays in triplicate. We then analyzed the results using a quartile-based threshold method to account for nonnormal data distribution and control for false positives (Fig. 1A). We identified 79 host genes that, when silenced, consistently and significantly affected fungal adherence, uptake, or both (Table S1). The goal of our screen was to identify host factors with specific roles in interactions with *C. neoformans* rather than in general phagocytosis. To rule out the latter, we compared the uptake of cryptococcal cells by siRNA-treated THP-1 cells to that of inert particles (1- $\mu$ m fluorescent latex beads; Fig. 1B). Of the 79 candidates assayed, 25 showed differences in uptake or adherence with the yeast but not with latex beads (Table S2). We next tested these 25 targets with three additional organisms: the pathogenic yeast *Candida albicans*, the model yeast *Saccharomyces cerevisiae*, and the bacterium *Escherichia coli*. Four host genes showed specific alterations in uptake or adherence of *C. neoformans* compared to the other particles (highlighted in Table S2). Results for one of these genes (CaMK4) is shown in Fig. 1C.

**CaMK4 influences cryptococcal infection.** We chose CaMK4 for follow-up, because silencing the corresponding gene yielded the most marked and reproducible reduction in cryptococcal uptake and it had not previously been implicated in cryptococcal interactions with host macrophages. To further investigate its role in *C. neoformans*

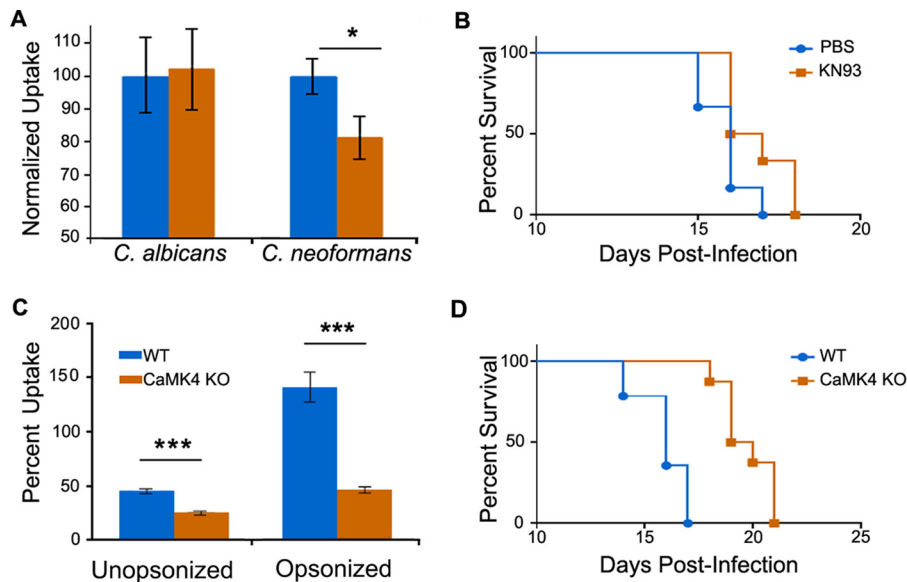

**FIG 1** RNAi screening for regulators of fungal uptake. (A) Fungal uptake by THP-1 cells treated with siRNA pools targeting CamK4 (orange) or 867 other kinases and phosphatases (dark blue symbols), no siRNA (light blue symbols), or scrambled siRNA (white symbols); see Materials and Methods for additional controls. The red lines indicate the upper and lower boundaries of the plate averages using the quartile-based threshold method. Candidate genes outside those bounds (79) advanced to the next round of screening. (B) A second round of screening identified gene depletions that altered uptake of cryptococcal cells but not of an inert particle control (latex beads). Results were normalized to no-siRNA control assays with the appropriate particle and assessed by Student's *t* test. Controls (as described for panel A) fitted to the diagonal (red line) had an  $R^2$  value of 0.76. (C) THP-1 cells were treated with siRNA targeting CaMK4, and uptake of *C. neoformans* (Cn), *C. albicans* (Ca), *S. cerevisiae* (Sc), *E. coli* (Ec), or latex beads (LB) was assayed. Phagocytosis of *C. neoformans* was significantly decreased compared to that of the other particles ( $P < 0.1$  for *C. albicans* and  $P < 0.05$  for all other particles). Red line, normalized uptake value of 1.

infection, we treated THP-1 cells with KN93, a competitive inhibitor of CaMK4 and a related kinase, CaMK2 (17). Treatment with 10 nM KN93 did not compromise host cell growth or viability (not shown), but it did specifically reduce *C. neoformans* uptake in standard assays, similar to the effects of silencing. It had no effect on the uptake of *C. albicans* (Fig. 2A) or latex beads (not shown). We also tested whether treatment with this compound would alter the survival of mice after intranasal infection with *C. neoformans*. We found that treatment of C57BL/6 mice with KN93 modestly but significantly increased survival compared to control treatment with phosphate-buffered saline (PBS) alone (Fig. 2B and Fig. S2).

KN93 inhibits both CaMK4 and CaMK42. To more definitively address the role of CamK4 in *C. neoformans* infection, we isolated peritoneal macrophages from WT and CaMK4<sup>-/-</sup> mice and compared them in uptake assays. Consistent with the results of siRNA silencing and KN93 treatment experiments, primary macrophages deficient in CaMK4 showed significantly reduced uptake of *C. neoformans* compared to that of WT macrophages (Fig. 2C). Based on this defect, we next examined infection kinetics in CaMK4<sup>-/-</sup> mice. Notably, these mice survived significantly longer than WT mice (Fig. 2D and Fig. S2). Interestingly, despite the survival difference, total fungal burden in lung, spleen, and brain did not differ between the two strains at any time after infection (Fig. S3).

**The extended survival of CaMK4<sup>-/-</sup> mice is not due to differences in cytokine levels or immune cell infiltrate.** Our infection studies indicated that decreased fungal burden was not responsible for the prolonged survival of CaMK4<sup>-/-</sup> mice. We wondered whether the survival difference was instead due to adverse effects of the host immune response, which is stimulated by wild-type infection. We first tested this by cytokine profiling of WT and CaMK4<sup>-/-</sup> mice infected with KN99 $\alpha$ . Analysis of pulmo-

**FIG 2** Inhibition or knockout of CamK4 influences fungal uptake and pathogenesis. (A) THP-1 cells were assayed for uptake of the organisms indicated after treatment with PBS alone (blue) or 10 nM KN93 in PBS (orange). The averages and standard errors of the means (SEM) from five independent studies are shown (\*,  $P < 0.05$  by Student's  $t$  test). (B) Survival of C57BL/6 mice treated with either PBS alone (blue) or with 250  $\mu\text{g/g}$  body weight KN93 in PBS (orange). Mice were treated 1 day prior to infection with  $5 \times 10^4$  cryptococci and three times a week postinfection. Results are representative of two independent experiments with 6 mice per group;  $P < 0.05$  by log-rank test. (C) Peritoneal macrophages from WT (blue) and CaMK4<sup>-/-</sup> (orange) mice were assayed for uptake of *C. neoformans*. The averages and SEM from four independent studies are shown (\*\*\*,  $P < 0.0001$  by Student's  $t$  test). (D) Wild-type (WT;  $n = 16$ ) and CaMK4 knockout ( $n = 9$ ) mice were infected with *C. neoformans* and monitored as detailed in Materials and Methods. Results are representative of four independent experiments;  $P < 0.05$  by log-rank test.

nary homogenates from naive mice and from infected mice on days 7 and 14 postinoculation revealed no significant differences in any of the 23 cytokines or chemokines assayed (Table 1).

We next assayed wild-type and CaMK4<sup>-/-</sup> mice for differences in infiltrating immune cells after infection. To do this, we isolated pulmonary leukocytes on days 7 and 14 postinoculation and used flow cytometry to characterize the immune cells recruited to the lungs. We observed no significant differences in percent (Fig. 3) or absolute number (not shown) of any of the cell types assayed. The extended survival of CaMK4<sup>-/-</sup> mice thus is not likely due to changes in cytokine or immune cell profiles.

**CaMK4 ablation leads to reduced pattern recognition receptor expression.** Our studies using RNAi, a kinase inhibitor, and knockout mice all showed that lowering CaMK4 activity leads to reduced cryptococcal engulfment by host phagocytes. Because lack of CaMK4 did not alter fungal burden, cytokine profile, or leukocyte distribution during infection, we hypothesized that the connection between this regulatory protein and fungal uptake occurs at the level of immune cell surface receptor expression. To test this, we used surface staining and flow cytometry to analyze pulmonary leukocytes from wild-type and CaMK4<sup>-/-</sup> mice on day 7 postinoculation for expression of 10 receptors that have been implicated in interactions with cryptococcal cells. In CaMK4<sup>-/-</sup> mice we observed a significant reduction in the percentage of exudate/recruited macrophages (F4/80<sup>+</sup>, CD11b<sup>+</sup>, and CD11c<sup>+</sup>) positive for CD282/TLR2, Dectin-1, and CD206/mannose receptor and the percentage of dendritic cells (F4/80<sup>-</sup>, CD11b<sup>+</sup>, and CD11c<sup>+</sup>) positive for CD206 (Fig. 4), although for those cells that were positive, the fluorescence intensity was comparable (Fig. 5). In contrast, we found no significant differences in receptor expression between uninfected WT and CaMK4<sup>-/-</sup> mice (Fig. 5). Thus, the reduced fungal uptake we observe *in vitro* likely is caused by surface receptor expression that is altered in the absence of CaMK4.

**DISCUSSION**

Understanding host-pathogen interactions is vital to the development of new drugs and/or immune therapies. *C. neoformans*, a facultative intracellular pathogen, interacts with multiple facets of the immune system. Because the patients most susceptible to this infection are severely immunocompromised, identifying key host factors potentially can lead to ways to tip the balance in favor of the host. One way to identify such host factors is by screening host genes for their impact on pathogen interactions.

**FIG 3** CaMK4 knockout mice exhibit no difference in leukocyte infiltration in response to *C. neoformans* infection. Shown are leukocyte profiles of WT (blue circles) and CaMK4 knockout mice (orange squares) infected with 10<sup>4</sup> *C. neoformans* KN99α for the times shown. Each symbol represents data from an individual mouse. Results from 2 independent experiments with 4 to 5 mice per group per time point are shown; means ± SEM are also plotted. Leukocytes were labeled with antibodies to identify B cells (CD45<sup>+</sup> and CD19<sup>+</sup>), CD4<sup>+</sup> T cells (CD45<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>-</sup>), CD8<sup>+</sup> T cells (CD45<sup>+</sup>, CD8<sup>+</sup>, and CD4<sup>-</sup>), DCs (CD45<sup>+</sup>, CD11b<sup>+</sup>, CD11c<sup>+</sup>, and F4/80<sup>-</sup>), eosinophils (CD45<sup>+</sup>, CD11b<sup>+</sup>, and SiglecF<sup>+</sup>), exudate or recruited macrophages (CD45<sup>+</sup>, CD11b<sup>+</sup>, CD11c<sup>+</sup>, and F4/80<sup>+</sup>), macrophages (CD45<sup>+</sup>, CD11b<sup>+</sup>, CD11c<sup>-</sup>, and F4/80<sup>+</sup>), and polymorphonuclear leukocytes (PMNs; CD45<sup>+</sup>, CD11b<sup>+</sup>, and Ly6G<sup>hi</sup>) and then analyzed by flow cytometry (see Table S3 in the supplemental material for antibodies and Fig. S4 for gating strategy).

**FIG 4** Leukocytes from  $CaMK4^{-/-}$  mice show reduced expression of PRRs implicated in cryptococcal recognition. PRR profiling of leukocytes from WT (blue circles) and  $CaMK4$  knockout (orange squares) mice 7 days after infection with  $10^4$  *C. neoformans* KN99 $\alpha$ . Antibody labeling and flow cytometry was used to classify pulmonary leukocytes as DCs ( $CD45^+$ ,  $CD11b^+$ ,  $CD11c^+$ , and  $F4/80^-$ ), exudate or recruited macrophages (Ex M $\phi$ ) ( $CD45^+$ ,  $CD11b^+$ ,  $CD11c^+$ , and  $F4/80^+$ ), or macrophages/monocytes ( $CD45^+$ ,  $CD11b^+$ ,  $CD11c^-$ , and  $F4/80^+$ ) and to assess PRR expression. Symbols indicate data from individual mice in 2 independent experiments with 4 to 5 mice per group; means  $\pm$  SEM are also shown (\*,  $P < 0.05$ ; \*\*,  $P < 0.01$  by Student's *t* test).

We probed these complex interactions using siRNA gene silencing in a human macrophage-like cell line.

Qin et al. previously performed a manual siRNA screen for host factors involved in cryptococcal uptake (18), although multiple key features distinguish our study from that work. Most central to the project design, the prior study targeted genes that were preselected for known involvement in membrane traffic, membrane remodeling, phagosome establishment, or phagosome maturation and thus were expected to affect fungal engulfment or survival. The screen also used insect cells, rather than mammalian cells, to represent the host. Finally, fungi in the earlier study were not opsonized, although some form of opsonization likely occurs in all disease contexts (14), and were not exposed to host-like growth conditions (e.g.,  $37^\circ\text{C}$  and  $5\% \text{CO}_2$ ) that are known to dramatically alter virulence factor expression (19) and engulfment by host cells (16). A subset of the genes targeted by Qin et al. did, as hypothesized, alter fungal uptake; several of them, initially selected for their role in autophagosome biogenesis, were also shown to influence uptake and/or replication of unopsonized fungi in a mammalian system (murine RAW264.7 macrophages).

We performed an automated, unbiased screen of RNAi-treated human phagocytes, which were exposed to fungi opsonized with human serum under host-like conditions. We targeted 868 genes encoding two classes of host proteins that frequently act in regulatory processes, kinases and phosphatases, because we hypothesized that some of these would regulate host-fungus interactions. From 79 first-round hits of this screen, we refined our results based on specificity for *C. neoformans* interactions.

Of the four cryptococcus-specific genes that we identified, one prominent hit was the gene encoding calcium/calmodulin-dependent protein kinase 4 (CaMK4). CaMKs are serine/threonine kinases sensitive to changes in intracellular calcium. They are involved in cellular processes ranging from gene regulation, apoptosis, and cytokine release to differentiation and survival of T-lymphocytes and monocyte-derived cells (20, 21). Interestingly, a recent study based on phosphoproteomic analysis identified another member of this family, CaMK2, as a protein involved in *C. neoformans* phagocytosis (22). This work did not yield CaMK2, which may reflect the very distinct approaches of the two studies.

Multiple isoforms of CaMK display tissue-specific expression, with CaMK4 predominantly expressed in cells of the nervous and immune systems (20, 21). Both of these are significant lineages for cryptococcal infection, as *C. neoformans* shows tropism for the central nervous system. CaMK4 occupies a key position between upstream  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase kinase (CaMKK) and downstream transcription factors in a  $\text{Ca}^{2+}$ /calmodulin-regulated pathway or CaM kinase cascade (20). Once activated by phosphorylation, CaMK4 translocates to the nucleus and can phosphorylate multiple proteins, including CREB (21).

In phagocytic cells CaMKs are involved in several PRR signaling pathways, including those initiated by TLR2 and TLR4, where they act to modulate the transduced signal by phosphorylating CREB (20, 23). CREB activation is also involved in expression and signaling of the C-type lectin receptors Dectin-1 and CD206/mannose receptor (24, 25). We observed a significant reduction in cells positive for TLR2, Dectin-1, and CD206 across multiple phagocytic cell types during infection in CaMK4<sup>-/-</sup> mice compared to WT mice (Fig. 4). Notably, all three of these PRRs can recognize cryptococcal cells. TLR2 recognizes components of the cryptococcal capsule (26–28). Peripheral blood mononuclear cells (PBMCs) isolated from patients with cryptococcal meningitis also exhibit significantly less TLR2 than healthy control PBMCs, which has been interpreted as demonstrating a role for TLR2 in cryptococcal infection (29). TLR2 in combination with Dectin-1 can recognize fungal  $\beta$ -glucan and is important in protection against *Aspergillus*, *Candida*, and *Pneumocystis* infections (30–32). While Dectin-1 alone can recognize cryptococcal cells, there is no significant difference in disease progression in Dectin-1 KO mice compared to that of WT mice, suggesting that Dectin-1 is not required for host defense against *C. neoformans* (33, 34). CD206 recognizes heavily mannoseylated cryptococcal mannoproteins (35), and the corresponding knockout mice succumb to *C. neoformans* infection significantly faster than WT mice (36). Increased surface expression of CD206, which is upregulated on M2 macrophages, results in increased phagocytosis, consistent with our results, but is also accompanied by decreased intracellular killing and tumor necrosis factor alpha (TNF- $\alpha$ ) production (36). Although the roles of these three PRRs are complex, the changes observed in their expression could explain the reduced uptake of cryptococci by cells lacking CaMK4.

As discussed above and recently reviewed (15), host phagocytes play disparate roles in *C. neoformans* infection. These range from killing the fungi to providing them with a replicative niche or acting as Trojan horses to convey them to the brain, but all depend on interactions between the yeast and host cells. Alanio et al. tested the relationship between cryptococcus-macrophage interactions and disease outcome by measuring the engulfment and intracellular proliferation of clinical isolates upon exposure to murine phagocytes *in vitro* (37). They found that low phagocytic and intracellular proliferation indices of *C. neoformans* strains correlated with longer patient survival (37). The reduced uptake of fungi by innate immune cells with lower CaMK4 (Fig. 1A) therefore might account for the increased survival of CaMK4<sup>-/-</sup> mice com-

pared to that of WT mice. Given this difference in survival, we were surprised that we observed no significant change in fungal burden between the WT and the CaMK4<sup>-/-</sup> mice (see Fig. S3 in the supplemental material). Importantly, assessment of organ burden by CFU (as is standard in the field and done here) does not distinguish between free and internalized fungi. It is possible that this is a key parameter in infection outcome.

CaMK4 has been implicated in neurological disorders (38, 39) and the level of Foxp3(+) regulatory T cells (Treg) (40). We considered the possibility that changes in the neuroimmune response or in the number of pulmonary Treg in CaMK4<sup>-/-</sup> mice could explain the difference in mouse survival, but we found no significant differences in these parameters (data not shown). Finally, it is also possible that the global CaMK4 deletion influences mouse survival by altering processes other than those of the hematopoietic compartment; these remain to be investigated.

In this study, we combined siRNA screening and an automated imaging-based assay to identify host phosphatases and kinases that are involved in *C. neoformans* internalization by human phagocytes. We identified four genes that, when silenced, demonstrated *C. neoformans*-specific alterations in uptake and verified the role of one of them *in vivo*. Unbiased strategies thus may be a powerful tool for identifying host factors involved in cryptococcal pathogenesis and potentially inform efforts to develop improved therapies that are desperately needed.

## MATERIALS AND METHODS

**Ethics statement.** All animal protocols were reviewed and approved by the Animal Studies Committee of the Washington University School of Medicine and conducted according to National Institutes of Health guidelines for housing and care of laboratory animals. Human serum was obtained from healthy donors with informed consent under a protocol approved by the Washington University in St. Louis Institutional Review Board (IRB).

**Reagents.** Unless otherwise stated, chemicals were purchased from Sigma-Aldrich (St. Louis, MO), tissue culture medium from Invitrogen (Grand Island, NY), and plasticware from Fisher Scientific (Pittsburgh, PA).

**Strains and media.** *Cryptococcus neoformans* strains H99 $\alpha$  (from Joe Heitman) and KN99 $\alpha$  (from Kirsten Nielsen), *Saccharomyces cerevisiae* strain W303 (from Randy Schekman), and a *Candida albicans* *efg1 $\Delta$  cph $\Delta$*  strain (a nonhyphenating mutant; from Aaron Mitchell) were recovered from 15% glycerol stocks stored at -80°C and maintained on YPD plates (1% yeast extract, 2% peptone, 2% dextrose, and 2% Bacto agar). For all studies yeast cells were grown for 15 to 17 h at 30°C with shaking in YPD broth, collected by centrifugation, washed three times with sterile phosphate-buffered saline (PBS), and counted on a Cellometer Auto M10 (Nexcelom Bioscience, Lawrence, MA).

**Cell culture.** Mammalian cells were grown at 37°C and 5% CO<sub>2</sub>. THP-1, a male human monocytic cell line (ATCC TIB-202), was cultured in RPMI 1640 with 10% heat-inactivated fetal bovine serum (FBS), 100  $\mu$ g/ml penicillin, 100 U/ml streptomycin, 1 mM sodium pyruvate, and 48  $\mu$ M  $\beta$ -mercaptoethanol and passaged every 3 days to maintain cell density of  $1.5 \times 10^5$  to  $9 \times 10^5$ /ml. Prior to uptake assays, cells were seeded in flat-bottomed polystyrene 96-well microtiter plates (Costar) at  $1.5 \times 10^4$  cells/well in THP-1 differentiation medium (the growth medium described above with 0.2  $\mu$ g/ml phorbol 12-myristate 13-acetate) and grown for 48 h.

**RNAi library testing.** For treatment with Qiagen siRNA libraries targeting human phosphatases and kinases (v 4.0), THP-1 cells were seeded in 96-well plates using a BioMek FX laboratory automation workstation. Pools of two siRNAs per target (10 nM final concentration) were added to each well with 100  $\mu$ l of Polyplus INTERFERin transfection reagent (Polyplus Transfection, New York, NY), and the cells were incubated for 2 h before the addition of THP-1 differentiation medium and continued growth for 48 h. Host cell viability was monitored using alamarBlue (Life Technologies). Twenty-four hours prior to uptake assays the transfected cells were washed and the medium replaced with RPMI 1640 alone to induce starvation. For some studies, THP-1 cells were treated with 10 nM CamK4 inhibitor KN93 (dimethyl sulfoxide [DMSO]-soluble form; Sigma) for 24 h prior to uptake assays (during the starvation phase). Cells were then washed and fresh RPMI 1640 was added before initiation of the assays.

**Uptake assays.** Four particles were used for uptake assays: *C. neoformans* cells stained for 30 min at room temperature (RT) with Lucifer yellow (Sigma) in McIlvaine's solution (pH 6.0; final concentration, 100  $\mu$ g/ml); *S. cerevisiae* and *C. albicans* stained for 30 min at RT with FUN-1 (2.0  $\mu$ l of 10 mM stock; Invitrogen) in 100  $\mu$ l 1 $\times$  PBS; and fluorescent yellow-green 1- $\mu$ m latex beads (Sigma). All particles were opsonized for 30 min at 37°C with 40% human serum before addition at a multiplicity of infection (MOI) of 16 to the plates of transfected and starved THP-1 cells, and the plates then were incubated for 1 h at 37°C and 5% CO<sub>2</sub>. Human serum was obtained from individual healthy volunteers by following a protocol approved by the Washington University School of Medicine IRB.

Postinfection, plates were processed as described in Srikanta et al. (16). Briefly, they were washed with a BioTek ELx405 microplate washer (BioTek, Winooski, VT) to remove nonadherent cells, fixed

in 4% formaldehyde, and permeabilized with 0.1% saponin. Host cells then were stained with 2  $\mu$ g/ml 4',6-diamidino-2-phenylindole (DAPI) to label host nuclei and 250 ng/ml CellMask plasma membrane deep red to stain host cell bodies (both from Sigma). Plates were imaged using an IN Cell analyzer (GE Healthcare) with scanning on 3 channels (wavelengths of 360/460, 475/535, and 620/460 nm to detect DAPI, Lucifer yellow, and CellMask, respectively). Fifteen to 20 images were captured for each channel/well and analyzed using the IN Cell Developer Toolbox (GE Healthcare). Each sample was assayed in one well in the same position on 3 separate 96-well plates, and all experiments were repeated at least twice. All studies included controls for uptake (fungi with or without serum opsonization) and for RNAi treatment (no siRNA, scrambled siRNA, and siRNA targeting proteins required for general phagocytosis).

**Quantitative real-time PCR.** Total RNA was isolated using the RNeasy Plus minikit (Qiagen), and first-strand cDNA was synthesized using SuperScript II (Invitrogen) per the manufacturer's instructions. mRNA levels were quantified with SYBR green-based detection using a Bio-Rad CFX96 instrument and 40 cycles of PCR (94°C for 15 s, 60°C for 30 s, and 72°C for 30 s). Gene expression was normalized to *ACT1* levels and expressed as a percentage of WT control expression.

**Pulmonary infections.** Four- to 6-week-old female C57BL/6J mice or CaMK4<sup>-/-</sup> mice (The Jackson Laboratory, Bar Harbor, ME) were anesthetized by intraperitoneal (i.p.) injection (of 150  $\mu$ l of 2 mg/ml xylazine [VEDCO] and 10 mg/ml of ketaset [Fort Dodge Animal Health]) and intranasally inoculated with the indicated number of CFU (verified by quantitative culture on YPD agar) of *C. neoformans* strain KN99 $\alpha$  in 50  $\mu$ l of sterile PBS. The mice were fed *ad libitum* and monitored daily for symptoms. For organ burden, cytokine analysis, and flow cytometry studies, mice were euthanized at specific time points postinoculation by CO<sub>2</sub> inhalation, and the lungs, brain, and spleen were harvested. For survival studies, mice were sacrificed when body weight fell below 80% of peak weight. For some survival studies, mice were injected i.p. with water-soluble KN93 (250  $\mu$ g/g body weight; EMD Millipore) in 100  $\mu$ l of PBS or PBS alone three times a week, beginning 1 day prior to infection.

**Pulmonary leukocyte isolation.** For leukocyte isolation, lungs were enzymatically digested at 37°C for 30 min in 10 ml of digestion buffer (RPMI 1640 containing 1 mg/ml of collagenase type IV). The digested tissues then were successively passed through sterile 70- and 40- $\mu$ m-pore nylon strainers (BD Biosciences, San Jose, CA). Erythrocytes in the strained suspension were lysed by incubation in NH<sub>4</sub>Cl buffer (0.859% NH<sub>4</sub>Cl, 0.1% KHCO<sub>3</sub>, 0.0372% Na<sub>2</sub>EDTA; pH 7.4; Sigma-Aldrich) for 3 min on ice, followed by the addition of a 2-fold excess of PBS. The unlysed leukocytes then were collected by centrifugation, resuspended in sterile PBS, and counted with a Cellometer Auto M10 (Nexcelom Bioscience).

**Isolation and assay of peritoneal macrophages.** Four- to 6-week-old female mice were injected i.p. with 1 ml 5 mM sodium periodate (Sigma) in sterile PBS to induce cell recruitment into the peritoneal cavity. Mice were euthanized 72 h postinjection, and peritoneal lavage was performed with ice-cold sterile PBS. Macrophages were isolated from the lavage fluid by positive selection using biotinylated  $\alpha$ -F4/80 antibody (eBioscience) and  $\alpha$ -biotin-conjugated magnetic beads (Miltenyi Biotec). Uptake assays were performed as described above, except that C57BL/6 mouse serum was used for opsonization.

**Flow cytometry.** All flow cytometry steps were performed at 4°C. Pulmonary leukocytes in PBS were stained using the LIVE/DEAD fixable blue dead cell stain kit (Invitrogen, Carlsbad, CA) for 30 min. Following incubation, samples were washed and resuspended at 10<sup>7</sup>/ml in 100  $\mu$ l PBS plus 2% fetal bovine serum (fluorescence-activated cell sorting buffer), and 100  $\mu$ l was dispensed into wells of a 96-well U-bottom plate. Samples where Fc receptors were not to be directly analyzed then were incubated with CD16/CD32 (Fc block; BD Biosciences, San Jose, CA) for 5 min. For flow cytometry, cells next were incubated with the optimal concentrations of fluorochrome-conjugated antibodies (see Table S3 in the supplemental material for antigen, clone, and source) in various combinations for 30 min, washed, and fixed in 2% ultrapure formaldehyde. For data acquisition, >50,000 events were collected on a BD LSRFortessa X-20 flow cytometer (BD Biosciences, San Jose, CA), and the data were analyzed with FlowJo V10 (TreeStar, Ashland, OR).

**Cytokine analysis.** Cytokine levels in lung tissues were analyzed using the Bio-Plex protein array system (Bio-Rad Laboratories, Hercules, CA) as described previously (41). Briefly, lung tissue was excised and homogenized in ice-cold PBS (1 ml) and mixed with an equal volume of PBS containing 2 $\times$  Pierce protease inhibitors (Thermo Scientific, Rockford, IL) and 0.05% Triton X-100, and the samples were clarified by centrifugation. Supernatant fractions from the pulmonary homogenates then were assayed using the Bio-Plex Pro mouse cytokine 23-plex (Bio-Rad Laboratories) for the presence of interleukin-1 $\alpha$  (IL-1 $\alpha$ ), IL-1 $\beta$ , IL-2, IL-3, IL-4, IL-5, IL-6, IL-9, IL-10, IL-12 (p40), IL-12 (p70), IL-13, IL-17A, granulocyte colony-stimulating factor (G-CSF), granulocyte monocyte colony-stimulating factor (GM-CSF), interferon gamma (IFN- $\gamma$ ), CXCL1/keratinocyte-derived chemokine (KC), CCL2/monocyte chemoattractant protein-1 (MCP-1), CCL3/macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ), CCL4/MIP-1 $\beta$ , CCL5/RANTES, and TNF- $\alpha$ .

**Statistics.** All *in vitro* experiments were performed independently in triplicate. Candidates from the RNAi screen were assessed using the quartile-based threshold method described previously (42). To compare results between experiments, the data from each plate were normalized to the plate controls. Significance was assessed using the Student *t* test for individual paired comparison and by one-way analysis of variance and Tukey's test when multiple groups were compared. Mouse survival was analyzed using Kaplan-Meier analysis and log-rank statistics. All statistical analyses were confirmed using GraphPad Prism software, version 6.0 (GraphPad Software). *P* values of <0.05 were considered significant.

## SUPPLEMENTAL MATERIAL

Supplemental material for this article may be found at <https://doi.org/10.1128/IAI.00195-17>.

**SUPPLEMENTAL FILE 1**, PDF file, 1.0 MB.

## ACKNOWLEDGMENTS

We acknowledge the Center for Human Immunology and Immunotherapy Programs and the High-Throughput Screening Center at Washington University Medical School, where flow cytometry and screening were performed, respectively. We also thank Jayne Marasa and members of the Doering laboratory for helpful discussions, Mary Dinauer and Rachel Idol for assistance with peritoneal macrophages, and Joe Heitman, Aaron Mitchell, Kirsten Nielsen, and Randy Schekman for yeast strains.

These studies were supported by NIH grants AI102882 and AI078795 to T.L.D. D.S. was partially supported by F32 AI100481 and T32 AI007172, and C.R.H. was partially supported by T32 AI007172. S.A.K. was supported by R01 HL105427.

We have no conflicts of interest to declare.

D.S. and T.L.D. conceived of the project; D.S., C.R.H., and M.W. performed experiments; D.S., C.R.H., S.A.K., and T.L.D. analyzed data; and D.S., C.R.H., and T.L.D. wrote the text and all authors reviewed it.
