Abstract

We sought to determine whether ambient air pollution is associated with interstitial lung abnormalities (ILA) and high attenuation areas (HAA), which are qualitative and quantitative measurements of subclinical ILD on computed tomography.

We performed analyses of 6813 community-based dwellers enrolled in the Multi-Ethnic Study of Atherosclerosis (MESA), a U.S.-based prospective cohort study. We used cohort-specific spatiotemporal models to estimate predictions of ambient pollution (PM_{2.5}, NO_x, NO₂ and O₃) at each home. Participants underwent serial assessment of HAA by cardiac CT-scan and a subset of participants was assessed for ILA using full lung CT scan at 10 year follow-up. We used multivariable logistic regression and linear mixed models adjusted for age, sex, ethnicity, education, tobacco use, scanner technology and study site.

The odds of ILA increased 1.62-fold per 40ppb increment in NO $_{\rm X}$ (95%CI 0.97 to 2.71, p-value 0.06), and were strongest in non-smokers (2.60-fold increase per 40ppb increment in NO $_{\rm X}$, 95% CI 1.20 to 5.61, p-value 0.02). HAA increased by 0.54% per year per 5µg/m³ increment in PM $_{\rm 2.5}$ (95%CI 0.02% to 1.10%, p-value 0.04) and by 0.55% per year per 40ppb increment in NO $_{\rm X}$ (95%CI 0.08% to 1.00%, p-value 0.02).

Ambient air pollutants were associated with measurements of subclinical ILD.

epidemiology; air po	llution; interstitial l	ung disease; sul	oclinical	

Introduction

Air pollution is a risk factor for adverse respiratory outcomes. Many studies have shown associations between pollution exposure and the incidence and/or progression of multiple pulmonary diseases, including asthma, ¹ COPD, ² bronchiectasis, ³ respiratory infections, ⁴ chronic lung allograft dysfunction ⁵ and lung cancer. ⁶ There has been little research on whether air pollution may contribute to the etiology or accelerate the progression of interstitial lung diseases (ILDs), a heterogeneous group of chronic lung diseases characterized by inflammation and fibrosis of the pulmonary parenchyma that affect nearly 1 out of 200 older adults in the U.S. ⁷

ILD is often diagnosed after the onset of irreversible parenchymal fibrosis. Early symptoms are nonspecific and frequently attributed to other chronic pulmonary or cardiac diseases. Due to the late presentation of clinical manifestations and the presumed long latency between exposure and disease development, the underlying etiologies of many of the ILDs are unknown.

The growing recognition and identification of subclinical forms of ILD on CT scan provides a unique opportunity to investigate antecedent causes, rather than consequences, of ILD. Interstitial lung abnormalities (ILA), a visual assessment of early interstitial changes in nondependent portions of the lung, is a well validated qualitative measurement of subclinical ILD.⁸ A quantitative CT attenuation-based phenotype of subclinical ILD, termed high

attenuation areas (HAA), has also been shown to be a marker of subclinical lung inflammation and fibrosis. 9–11 Longitudinal studies estimate that 20% to 46% of participants with ILA have progressive imaging abnormalities, with approximately 4% developing features of usual interstitial pneumonia (UIP). 12 Even in the absence of clinical ILD, populations with subclinical ILD have more respiratory symptoms, physiologic decrements and higher mortality. 10,13,14 Inhalational exposures underlie the pathobiology of asbestosis, hypersensitivity pneumonitis and smoking-related ILDs. Ambient air pollutants may initiate or contribute to the cycle of alveolar injury, disordered repair and fibrosis seen in the ILDs, and have been associated with clinical exacerbations in interstitial fibrosis patients. 15 Air pollutants, including fine and ultrafine particles and traffic-related gases, can deposit throughout the airways and alveoli, causing either direct damage or triggering inflammation and oxidative stress. This could potentially result in alveolar cell injury or senescence, endothelial dysfunction, mononuclear cell interstitial inflammation and fibroblast proliferation.

The association between air pollutants and ILD has not been previously investigated in a population-based study. We hypothesized that exposure to air pollution would be associated with qualitative and quantitative measurements of subclinical ILD in community-dwelling adults.

METHODS

Study design and participants

The Multi-Ethnic Atherosclerosis Study (MESA) is a prospective cohort study funded by the National Heart Lung and Blood Institute to investigate subclinical cardiovascular disease. MESA and ancillary studies, MESA Lung and Air, are described in depth elsewhere and served as the sampling frame for this study. ^{10,16} Informed consent was obtained for all participants and the study was approved by the Institutional Review Board at collaborating centers.

Briefly, MESA enrolled 6,814 participants, ages 45–84 from six centers around the US: Baltimore, MD; Chicago, IL; Los Angeles County, CA; New York City, NY; St Paul, MN; and Winston Salem, NC. By study design, all participants were free of known cardiovascular disease at the start of the study; there were no selection criteria based on lung disease, respiratory symptoms or smoking history. Participants were recruited between 2000 through 2002, and underwent questionnaires regarding demographics, family history, medical history and lifestyle habits. At enrollment and during the four subsequent exams, participants had noninvasive assessment of cardiovascular status including cardiac CT scans - which image approximately 70% of the lung volume from main carina to lung. By design, all returning participants had a repeat cardiac CT scan at either exam 2 or 3, and 30% of the cohort had a third cardiac CT scan at exam 4. An additional subset of 3,137 participants underwent full lung or cardiac CT scan at exam 5.

The sampling scheme of participants that were included in our study is described in detail in the Supplementary Appendix.

Interstitial Lung Abnormalities

Full lung MESA CT scans were acquired in years 2010–12 (10-year follow-up) at suspended full inspiration using the MESA Lung/SPIROMICS protocol and images were reconstructed using 0.625 mm slice thickness. ¹⁷ One of five board-certified radiologists (inter-reader kappa 0.47 (0.14–0.80)) reviewed the full lung CT scans for ILA, which was defined as any scan read as "definite" ILD or "suspicious" for ILA. "Definite" ILD was defined as bilateral fibrosis in multiple lobes associated with honeycombing and traction bronchiectasis in a subpleural distribution. Scans were read as "suspicious" for ILA in the presence of ground-glass, reticular abnormality, diffuse centrilobular nodularity, honeycombing, traction bronchiectasis, non-emphysematous cysts or architectural distortion in at least 5% of nondependent portions of the lung. ¹⁸ Scans with solitary abnormalities that appeared in less than 5% of the lungs were read as "equivocal" for ILA and were excluded from the main analysis, as previously has been described. ¹⁰ In a sensitivity analysis, these "equivocal" scans were included in the group of participants without ILA.

High Attenuation Areas

HAA was measured on non-contrast cardiac CT scans performed at the MESA baseline visit and selected follow up exams using highly standardized protocols. ¹⁹ A prior validation study using MESA full lung scans showed that cardiac CT scans image approximately 65–70% of the total lung volume, capturing most of the lower lobes and excluding much of the lung apexes. Quantitative image attenuation was measured by trained readers using a modified version of the Pulmonary Analysis Software at the University of Iowa Imaging Lab (Iowa City, IA, USA) (intra-class correlation 0.93). HAA was defined as the percent of the imaged lung volume having attenuation values between –600 and –250 Hounsfield Units (HU). ^{9,10} This range of CT lung attenuation includes ground-glass and reticular abnormalities, and excludes denser areas such as atelectasis, medium and large blood vessels and pulmonary nodules. Percent emphysema was defined as the percentage of voxels below –950 HU.

Exposure assessment

Ambient air pollution exposure was estimated for each participant using residential history data (reported from 1980–2012) and spatio-temporal prediction models based on land use regression and geostatistical smoothing. These validated models are described in detail elsewhere. ^{20,21}

In brief, pollutants were measured at 27 long-term sites, 771 community snapshots and outside 697 participant homes between 2005–2009. Using these measurements to supplement pollution monitoring from the monitoring locations in the EPA Air Quality System, MESA Air developed community-specific spatio-temporal models incorporating geographic information and spatial smoothing. These models predict pollutant concentrations at residences for each two-week period between 1999–2012 and explain 90–97% of the variation in measurements at participant homes.

Given the expectation of a prolonged period of exposure contributing to the development of ILA, we estimated long-term ambient pollution exposure using ten-year averages of two-

week, residence-specific predictions prior to full lung CT scan. As a sensitivity analysis, we estimated twenty and thirty year exposure to $PM_{2.5}$ prior to full lung CT scan based on historic models of annual average exposure developed for periods pre-dating intensive PM monitoring.²² These long-term residential estimates used address-weighted averages of annual $PM_{2.5}$ concentration.

To model the progression of HAA, we estimated long-term exposures as the average of two-week residence-specific predictions from recruitment to follow-up. Year 2000 concentrations at participant's address at recruitment were used to model the baseline cross-sectional relationship.

Statistical Analyses

All statistical tests were performed in SAS version 9.3 (SAS Institute) using a two-tailed α = 0.05 to define statistical significance.

We used multivariable logistic regression to examine the associations between predicted 10year pollutant exposures and the odds of ILA on full lung CT scan at exam 5. Models were adjusted for age, gender, ethnicity, tobacco use (current smoking status and pack years) and site. In the main analysis, participants with "equivocal" ILA were excluded from the analysis and in a sensitivity analysis these participants were included in the group of participants without ILA. Sensitivity sub-analysis was performed with additionally adjustment for occupational exposures, a well-established risk factor for ILD. Occupational exposure was defined according to a previously developed and applied job exposure matrix (JEM) quantifying exposure to vapors, gas, dusts and fumes, but was not available for all participants.²³ Sensitivity analyses were performed using longer exposure periods by averaging 20 and 30-year estimates of PM_{2.5} derived from historic models pollution estimates when available. Other studies have shown differential effects on subclinical ILD based on smoking status, ethnicity and gender, so a priori, we decided to test for effect modification by these variables.^{9,11} Where stratified models showed different magnitudes of associations, we additionally tested for effect modification with a multiplicative interaction between pollutants exposure and potential effect modifier. We used the likelihood ratio test between the nested main effect and multiplicative models to test for statistical significance.

Linear mixed models were used to analyze the cross-sectional associations between air pollution and HAA at baseline examination and between air pollution and the rate of progression of HAA. HAA was log transformed in the model, and back transformed to obtain estimates of percent change. Repeated measurements were modeled as a function of study time, with time-varying exposures modeled as an interaction with time to examine associations between pollutant exposure and the linear rate of change of HAA over time. Participant-specific random intercepts and slopes were included. Models were adjusted for age, gender, race/ethnicity, educational attainment, JEM, height, BMI, waist circumference, smoking status, cigarette pack-years, glomerular filtration rate, total volume of image lung, percent emphysema on CT scan, CT scanner type and study site. Potential effect modification was examined by stratification on smoking status, gender and ethnicity.

RESULTS

3137 MESA participants, including some of the participants recruited under MESA Air, had a full lung CT scan that was assessed by a radiologist. 128 were not read for ILA and 34 had unreadable scans. As previously done, we further excluded 491 full lung CT scans that were read as "indeterminate" for ILA. 10 171 participants were missing ten year-pollutant estimates and 48 were missing other covariates, leaving 2265 participants with full lung CT scans in our final analysis of ILA (see appendix, figure S1). 6813 MESA participants had a baseline cardiac CT scan with valid HAA measurements. Of these, 5965 participants had at least one follow up cardiac CT scan during the study. 460 of these participants were missing either covariate information or pollutant estimates, leaving 5508 participants that were included in the longitudinal analysis of HAA progression (see appendix, figure S2). The mean number of cardiac CT scans per participant was 2.4. The mean follow-up time among the participants with at least 2 cardiac CT scans was 5.9 years, with a range of 0.9 to 11.4 years.

Baseline characteristics and air pollution estimates were similar in the cohorts included in the ILA and HAA analyses (Table 1). The mean age of the full cohort at baseline was 62 years (SD 10) and 3214 (47%) were male. Racial/ethnic differences were based on study design: 2621 (39%) participants were white, 1893 (28%) were African American, 1496 (22%) were Hispanic and 803 (11%) were Chinese American. 3085 (45%) participants had never smoked and 967 (14%) were current smokers.

Average air pollution concentration decreased over the study time, as described in detail elsewhere (16). Mean pollution concentration also varied by site, with the highest levels of $PM_{2.5}$ in Los Angeles and the highest levels of nitrates (NO_x and NO_2) in New York City. Pollutant levels were positively correlated with the exception of O_3 , which was negatively correlated with the other pollutants (see appendix Tables S1 and S2).

Associations of pollutants with Interstitial Lung Abnormalities

310 (9.9%) of the 3137 participants who underwent full lung CT scan had ILA: 289 (9.2%) had scans read as suspicious for ILD and 21 (0.67%) had scans that met standard criteria for a UIP pattern with bilateral fibrosis associated with honeycombing and traction bronchiectasis in a subpleural distribution. In multivariable-adjusted analyses, there were no significant associations between pollutant exposure and ILA in the overall analyses (Table 2; Figure 1). The odds of ILA increased 1.62-fold per 40ppb increment in NO $_{\rm X}$ (95%CI 0.97 to 2.71, p-value 0.06). In the *a priori* specified group of non-smokers, greater exposure to NO $_{\rm X}$ and NO $_{\rm 2}$, and lesser exposure to O $_{\rm 3}$ were each associated with an increased odds of ILA. Each 40 ppb increment in in NO $_{\rm X}$ was associated with a 2.6-fold greater odds of ILA (95% CI 1.20 to 5.61, p-value 0.02; p-value = 0.21 for interaction with smoking, appendix Table S4), while each 10 ppb increment in O $_{\rm 3}$ was associated with an odds ratio for ILA of 0.33 (95% CI 0.10 to 1.05, p-value 0.06; p-value = 0.27 for interaction with smoking, appendix Table S5).

In the sensitivity analysis which included participants with a CT scan initially read as "equivocal" in the control group of participants without ILA, associations between

pollutants and ILA were more robust (see appendix Table S5). For example, in this sensitivity analysis, the odds of ILA increased to 1.77-fold per 40ppb increment in NO_x (95% CI 1.06 to 2.95, p-value 0.03). Additional adjustment for occupational exposures led to similar findings (see appendix Table S6). Effect estimates were strongest among non-Hispanic whites, where there was a 3.13-fold increase in odds of ILA (95% CI 1.00 to 9.86, p-value 0.05; p-value = 0.9 for interaction between NO_x and non-Hispanic white) per 40ppb increase in NO_x exposure. Sensitivity analyses with 20 and 30-year pollutant estimates using a historic model for $PM_{2.5}$ yielded comparable qualitative results (see appendix Table S7).

Association with High Attenuation Areas

At recruitment, MESA participants had a mean HAA of 5.1% (3.1% SD) with a range of 1.4% to 46.6%. HAA decreased by an average of 0.35% (95% CI 0.21% to 0.48%) per year during the study time. In the primary analysis adjusted for potential confounders (Table 2), a $5\mu g/m^3$ increase in PM_{2.5} concentration was associated with a 0.54% (95% CI 0.02% to 1.10%, p-value 0.04) increase in HAA per year; a 40 ppb higher NO_x concentration was associated with a 0.55% (95% CI 0.08% to 1.0%; p-value 0.02) increase in HAA per year. Effect estimates for NO₂ concentration and progression of HAA were in a similar direction. There was a negative trend in the association between O₃ and HAA, however, this was inconsistent in subgroup analyses. There were no consistent cross-sectional associations between year 2000 pollution estimates and HAA (see Table S3 in online supplement).

DISCUSSION

We found that exposure to ambient nitrogen oxides was associated with a higher prevalence of ILA among non-smokers and with progression of HAA among both smokers and non-smokers. In addition, greater ambient PM_{2.5} exposure was associated with HAA progression. While less consistent, there was a trend towards an inverse association between greater O₃ concentrations and subclinical ILD. Ours is the first study to link air pollution with early evidence of lung inflammation and fibrosis on CT in community-dwelling adults, adding insight into the hypothesis that air pollution could contribute to ILD. The associations we found were strongest and most consistent for nitrogen oxide (NO_x), which is predominantly a mixture of nitrogen monoxide (NO) and nitrogen dioxide (NO₂). These results are similar to those of Johannson et al., in the sole prior study on the impact of air pollution on ILD.¹⁵ In a longitudinal study of 436 patients with idiopathic pulmonary fibrosis (IPF) from Seoul, South Korea, the authors showed that higher levels of NO₂ over the previous six weeks were associated with increased risk of an IPF exacerbation. Epidemiologic studies have also established the importance of nitrate exposure with other respiratory conditions, including reduced lung function,²⁴ asthma²⁵ and COPD.²⁶

 NO_x levels are highest in the near road environment, and may serve as a proxy for a suite of other traffic-related air pollutants (TRAP), including polyaromatic carbons, ultra-fine particles and other products of fossil fuel combustion. In comparison, O_3 tends to be lower in the near road environment – both due to O_3 scavenging by traffic-produced NO and because O_3 is a secondary pollutant, which is photochemically produced in the troposphere by the reaction of sunlight on volatile compounds.²⁷ This negative correlation could be

responsible for the trend towards an inverse effect that we saw with higher levels of O_3 . During inhalation, NO_x and TRAP combine with ammonia and other small particles, to penetrate deep within the bronchial tree. While there is some absorption throughout the respiratory tract, the primary site of injury is at the terminal bronchioles where particles can be phagocytized by airway macrophages, activate pulmonary nocioceptive fibers or cause direct epithelial damage. Mediated by the formation of reactive oxygen species, this leads to airway and systemic inflammation with ongoing cytokine and chemokine release. Murine models have demonstrated that nitrate exposure causes cellular injury, epithelial proliferation, hyperplasia, inflammation and fibrotic changes. In genetically susceptible humans, this could potentially initiate or contribute to the cycle of alveolar injury, disordered repair and fibrosis seen in the ILDs.

Our ILA findings were strongest in never smokers, a finding similar to other studies that have also reported pollution-related health effects predominantly in non-smokers. Previous authors have postulated that the detrimental effects of cigarette smoke may overwhelm the adverse consequences of ambient air pollution exposure. A similar phenomenon may drive the suggestion of a differential effect that we observed in ethnic groups with stronger effects from unmeasured healthcare disparities and other confounders compared to the effects due to air pollution. While our study had enough power to assess for associations with our main outcome of interest, our ability to show effect modification by these variables is limited.

The effect sizes we observed due to air pollution were small, but represent important subclinical changes in the lungs of asymptomatic community-dwelling U.S adults. We used sophisticated modelling to produce individual estimates of long-term exposure to air pollution, and investigated the effect of different lag times of exposure. By adjusting for site, we were able to eliminate unmeasured confounders between cities and focus on within city variations in pollutant levels.

This was an observational study with inherent limitations of exposure and outcome misclassification, residual confounding and the inability to infer causation. The longer term estimates of particulate matter exposure (twenty and thirty years) that were derived from historic models may be less accurate than our other pollutant estimates, which did not extrapolate to time periods with limited data and also benefitted from spatially intensive air pollution monitoring data. This non-differential exposure classification would be expected to weaken the strength of associations with ILA and HAA for the longer exposure periods. Our definition of subclinical ILD was based on radiologic findings rather than histologic changes. It is possible that our quantitative measurement of lung density included other pulmonary processes, such as edema, infection, or atelectasis. However, as described in our prior studies of this cohort, there was no evidence of confounding by cardiac function, obesity or the percentage of lung imaged. 10

In summary, we found that ILA was associated with long-term average exposure to oxides of nitrogen among non-smokers, and that HAA progression was associated with exposure to both oxides of nitrogen and fine particulates. More epidemiologic and translational studies will be needed to investigate the roles of individual pollutants and identify the potential biological pathways underlying these associations. Although definitive evidence is still

missing, this study provides supporting evidence that air pollution could be a potential risk factor for ILD. If proven, this would have important clinical implications for patients and serve to help inform public policy.

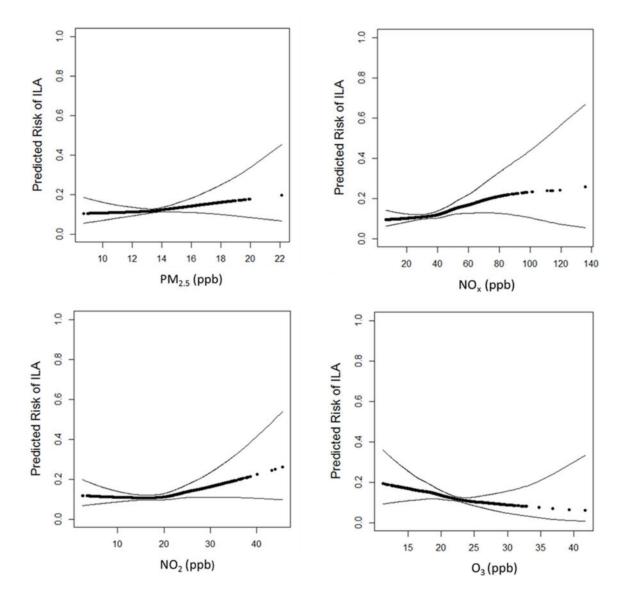

Figure 1. Predicted risk of Interstitial Lung Abnormalities with increasing levels of pollutants: $PM_{2.5}$, NO_x , NO_2 , O_3 . Effect estimates are derived from general additive models, with black points demonstrating the overall effect estimates and thin dashed lines representing the 95% confidence bands. All models adjusted for age, sex, race/ethnicity, tobacco use (pack years, smoking status) and study site.
