ABSTRACT In prion diseases, an abnormal isoform of prion protein (PrP^{Sc}) accumulates in neurons, astrocytes, and microglia in the brains of animals affected by prions. Detailed analyses of PrP^{Sc}-positive neurons and glial cells are required to clarify their pathophysiological roles in the disease. Here, we report a novel method for the detection of PrP^{Sc} in neurons and glial cells from the brains of prion-infected mice by flow cytometry using PrP^{Sc}-specific staining with monoclonal antibody (MAb) 132. The combination of PrP^{Sc} staining and immunolabeling of neural cell markers clearly distinguished neurons, astrocytes, and microglia that were positive for PrP^{Sc} from those that were PrP^{Sc} negative. The flow cytometric analysis of PrP^{Sc} revealed the appearance of PrP^{Sc}-positive neurons, astrocytes, and microglia at 60 days after intracerebral prion inoculation, suggesting the presence of PrP^{Sc} in the glial cells, as well as in neurons, from an early stage of infection. Moreover, the kinetic analysis of PrP^{Sc} revealed a continuous increase in the proportion of PrP^{Sc}-positive cells for all cell types with disease progression. Finally, we applied this method to isolate neurons, astrocytes, and microglia positive for PrP^{Sc} from a prion-infected mouse brain by florescence-activated cell sorting. The method described here enables comprehensive analyses specific to PrP^{Sc}-positive neurons, astrocytes, and microglia that will contribute to the understanding of the pathophysiological roles of neurons and glial cells in PrP^{Sc}-associated pathogenesis.

IMPORTANCE Although formation of PrP^{Sc} in neurons is associated closely with neurodegeneration in prion diseases, the mechanism of neurodegeneration is not understood completely. On the other hand, recent studies proposed the important roles of glial cells in PrP^{Sc}-associated pathogenesis, such as the intracerebral spread of PrP^{Sc} and clearance of PrP^{Sc} from the brain. Despite the great need for detailed analyses of PrP^{Sc}-positive neurons and glial cells, methods available for cell type-specific analysis of PrP^{Sc} have been limited thus far to microscopic observations. Here, we have established a novel high-throughput method for flow cytometric detection of PrP^{Sc} in cells with more accurate quantitative performance. By applying this method, we succeeded in isolating PrP^{Sc}-positive cells from the prion-infected mouse brains via fluorescence-activated cell sorting. This allows us to perform further detailed analysis specific to PrP^{Sc}-positive neurons and glial cells for the clarification of pathological changes in neurons and pathophysiological roles of glial cells.

KEYWORDS cell sorting, flow cytometry, prions

Prion diseases are neurodegenerative disorders that are pathologically characterized by the activation of astrocytes and microglia, vacuolation of neurons and neuropils, and the accumulation of an abnormal isoform of prion protein (PrP^{Sc}) in the central nervous system (CNS) of humans and animals affected by prions. PrP^{Sc} is a major

component of prions, the causative agent of prion diseases, and is generated from a cellular isoform of prion protein (PrP^C) that is encoded by the *Prnp* gene of the host. Accumulation of PrP^{Sc} is found as a diffused or plaque pattern in neuropils, neurons, and astrocytes in the brains of rodent models for prion diseases or found as a pattern associated with neurons, astrocytes, microglia, and blood vessels in the brains of cattle, deer, and sheep affected with prions [1]. Although the formation of PrP^{Sc} is considered to be associated closely with neurodegeneration [2–4], the mechanisms of neurodegeneration have not been elucidated fully at this time.

Previous studies have investigated the relationship between the formation of PrP^{Sc} and neurodegeneration [5–9]. PrP-deficient mice were resistant to prion infection and did not develop neuropathological changes after prion inoculation [5]. The transgenic mice expressing PrP^C specifically in neurons were susceptible to prion infection and reproduced the neurodegeneration [6]. Grafting the prion-infected brain tissues in the brain of PrP-deficient mice did not induce any degeneration in neurons of PrP-deficient mice, even though PrP^{Sc} in the grafts neighbored the neurons [7, 8]. Furthermore, neuron-specific depletion of the *Prnp* gene by conditional targeting largely prevented neurodegeneration, even though PrP^{Sc} existed in glial cells and extracellular spaces in those mice [9]. These reports indicate that neurodegeneration in prion diseases is associated closely with PrP^{Sc} formation in neurons.

Considering the findings that astrocytes and oligodendrocytes, as well as neurons, express PrP^C [10], the formation of PrP^{Sc} in glial cells may contribute to neurodegeneration. The accumulation of PrP^{Sc} was found in astrocytes at an early stage of infection after intracerebral inoculation of prions [11], and neurodegeneration was reproduced in the transgenic mice expressing PrP^C specifically in astrocytes [12]. However, ultrastructural pathologies specific to prion diseases were not found in astrocytes but were in neurons adjacent to PrP^{Sc} on astrocytes or to extracellular PrP^{Sc} released from astrocytes, although PrP^{Sc} is generated from PrP^C only in astrocytes of the transgenic mice [13]. Oligodendrocytes have been reported as resistant to prion infection [14]. Although Schwann cells have been reported as susceptible to prion infection [15], Schwann cells do not appear to be involved in the neurodegenerative process [16]. It was reported that prions propagate in microglia isolated from PrP^C-overexpressing mice [17] and that microglia isolated from CJD model mice possessed prion infectivity [18]. However, the formation or the presence of PrP^{Sc} in microglia does not appear to be required for neurodegeneration [19]. Taken together, these studies have shown the critical role of neuron-associated PrP^{Sc} in neurodegeneration rather than glial cell-associated PrP^{Sc}. In contrast, recent studies have proposed important roles for glial cells in PrP^{Sc}-associated pathogenesis. Glial cells could be involved in the intracerebral spread of prions [20, 21] and/or in the clearance of PrP^{Sc} from the brain [22]. Therefore, detailed analyses of glial cells and neurons that contain PrP^{Sc} are required to clarify the pathophysiological roles of glial cells in prion diseases.

Until recently, methods available for the cell-type-specific analysis of PrP^{Sc} in the brain were largely limited to immunohistochemistry or immunoelectron microscopy using anti-PrP antibodies [1, 23, 24]. Although these methods have contributed to the understanding of the cellular distribution and intracellular localization of PrP^{Sc}, assessments were made using semiquantitative measurements of the immunoreactivity of PrP^{Sc} and were based on observations by individual investigators, both of which are limiting factors for throughput and quantitative performance. Recently, methods for flow cytometric detection of misfolded proteins in cells were reported [25, 26]. On the other hand, immunolabeling of markers for neural cells enabled us to analyze neurons [27] and glial cells [28] from brain tissues separately using flow cytometry. The combination of immunolabeling of misfolded proteins and neural cell markers is thought to be applicable to the cell-type-specific analysis of misfolded proteins by flow cytometry with high throughput and better quantitative performance. Previously, we reported the specific detection of PrP^{Sc} in an immunofluorescence assay (IFA) using anti-PrP monoclonal antibody (MAb) 132 [29–31]. In the present study, we established a novel method for the detection of PrP^{Sc} in neurons and glial cells by flow cytometry using a

combination of PrP^Sc-specific staining and immunolabeling of neural cell markers. We also showed the utility of this method for isolating PrP^Sc-positive cells in the brain.

RESULTS

Flow cytometric detection of PrP^Sc in prion-infected cells. We previously reported that specific labeling of PrP^Sc with MAb 132 is applicable for immunocytochemistry on cells persistently infected with prions (31) and prion-infected primary neuronal cultures (30) after the fixed cells have been treated with guanidine thiocyanate (GdnSCN). We applied this method to detect PrP^Sc in a neuroblastoma cell line, Neuro2a (N2a-3), infected with prions by flow cytometry.

First, we compared the PrP signals between uninfected N2a-3 cells and N2a-3 cells persistently infected with a 22L prion strain (ScN2a-3-22L) using four anti-PrP antibodies with or without cell pretreatment with GdnSCN (Fig. 1A). Without GdnSCN pretreatment, PrP signals were detected by MAbs 106, 31C6, and 44B1 in both N2a-3 and ScN2a-3-22L cells, while PrP signals were hardly detected by MAb 132 (Fig. 1A, Gdn −). The GdnSCN pretreatment enhanced the signals of PrP in ScN2a-3-22L cells that were detected with MAb 132, and the mean fluorescence intensity (MFI) of PrP signals in ScN2a-3-22L cells was 4.4 times higher than those in N2a-3 cells (Fig. 1A, MFI ratio, Gdn +). The GdnSCN pretreatment enhanced PrP signals in ScN2a-3-22L cells by MAbs 106, 31C6, and 44B1 (Fig. 1A, Gdn +). The MFIs of PrP signals by these MAbs were much higher than that by MAb 132 (Fig. 1A). However, PrP^C was clearly detected in uninfected N2a-3 cells under the same conditions, thus the MFI ratios of PrP signals for these MAbs were smaller than that obtained by MAb 132 (Fig. 1A, MFI ratio, Gdn +). Consistent with flow cytometric detection, microscopic observation with MAb 132 showed granular PrP signals in ScN2a-3-22L cells but faint or no signals in N2a-3 cells (Fig. 1B). The MAbs 106, 31C6, and 44B1 stained intense PrP signals in ScN2a-3-22L cells; however, PrP signals were also detected at the plasma membranes and perinuclear regions in uninfected N2a-3 cells. Therefore, not the intense PrP signals but a trace or lack of PrP^C signals in uninfected cells by MAb 132 enabled us to distinguish PrP^Sc-positive cells from PrP^Sc-negative cells by flow cytometry.

To confirm the utility of MAb 132 for the flow cytometric detection of PrP^Sc in different prion strains or cell lines, we analyzed PrP signals in N2a-3 cells persistently infected with the Chandler prion strain (ScN2a-3-Ch) and GT1-7 cells persistently infected with the 22L prion strain (ScGT1-7-22L). Consistent with the detection of proteinase K (PK)-resistant PrP^Sc (PrP-res) by immunoblotting (Fig. 1C), ScN2a-3-Ch and ScGT1-7-22L cells were obviously positive for MAb 132, but PrP^C signals were hardly detected in the corresponding uninfected cells (Fig. 1D). These results indicated that PrP^Sc detection with MAb 132 using flow cytometry is applicable for different prion strains or cell lines.

Flow cytometric detection of PrP^Sc in neurons and glial cells from prion-infected mouse brain. Using PrP^Sc-specific staining with MAb 132, we attempted to detect PrP^Sc in neurons and glial cells isolated from mouse brains using flow cytometry. Isolation of adult CNS neurons is problematic because of the tight adhesion of cell bodies and thousands of synapses (32), and mature neurons are damaged easily by enzymatic dissociation and mechanical trituration during the isolation step. These factors increase the chance for cell death and thus hamper subsequent analysis (33). We then evaluated the viability of cells prepared from mouse brain with papain-based enzymes and mechanical trituration. Cell suspensions contained a considerable amount of cell debris. Therefore, the cell nuclei were stained with DRAQ5, a membrane-permeable DNA probe, to distinguish cell bodies from cell debris. In flow cytometric analysis, we selected events corresponding to cell bodies by gating events positive for DRAQ5 (Fig. 2A, DRAQ5 width and DRAQ5 height). Single events were gated based on forward scatter (FSC) and side scatter (SSC) profiles (Fig. 2A, FSC and SSC as well as SSC area and SSC height). Finally, to screen the dead cell population, we analyzed signals of propidium iodide (PI), a DNA probe impermeable to live cell membranes. The

FIG 1 Detection of PrP^{Sc} in prion-infected cells by flow cytometry. (A) Comparison of PrP^{C} detection in uninfected cells and PrP detection in infected cells with anti-PrP MAbs using flow cytometry. N2a-3 or ScN2a-3-22L cells were harvested with collagenase. The cells were fixed with 4% PFA in PBS and treated with 5 M GdnSCN (Gdn +) or remained untreated (Gdn −). The cells were stained with anti-PrP MAbs 106, 132, 31C6, and 44B1 and then subjected to flow cytometric analysis. In the histograms, red lines show the signals of ScN2a-3-22L cells, blue lines show signals of N2a-3 cells, and the black line and black dashed line show

(Continued on next page)

proportion of dead cells was less than 3.6% in the mock-infected mouse brain, indicating that cell damage by dissociation could be minimized with our method.

For flow cytometric analysis of cells prepared from the brain, removal of cell debris from samples was required using density gradient centrifugation, because excess debris prolongs measurement duration for this method. In addition to this step, pretreatment with GdnSCN after fixation of the cells was also necessary for the specific staining of PrP^{Sc} with MAb 132. These procedures potentially could influence the efficiency of cell labeling to distinguish the cell population; therefore, we assessed the effects of cell debris removal and GdnSCN pretreatment on a proportion of CD11b-positive microglia and glial fibrillary acidic protein (GFAP)-positive astrocytes in the brains of mock-infected or Chandler strain-infected mice in the early clinical stage of prion infection at 120 days postinoculation (dpi) (Fig. 2B). In the flow cytometric analysis, single events corresponding to cell bodies were gated using profiles of nuclear staining with 7-aminoactinomycin D (7-AAD), FSC, and SSC, as described for Fig. 2A. CD11b labeling showed a clear population of CD11b-positive cells and also showed an increase in the proportion of CD11b-positive cells in the Chandler-infected mouse (59.4%) compared with the mock-infected mouse (24.7%) (Fig. 2B, cell debris removal −, far right column). Signal intensities of GFAP in the CD11b-negative cell population in both mock- and Chandler-infected mice ranged over five orders of magnitude (Fig. 2B, cell debris removal −, far right column). Here, we identified GFAP-positive cell populations as only the cells that had strong GFAP signals, as described in previous reports (28, 34). The removal of cell debris increased the proportion of cell bodies labeled with 7-AAD from 0.7% to 3.5% and from 0.7% to 3.1% in mock-infected and Chandler strain-infected mice, respectively. This procedure did not influence the labeling efficiencies of CD11b and GFAP or the proportion of CD11b- and GFAP-positive cells (Fig. 2B, cell debris removal − and +). However, the GdnSCN treatment evidently decreased the intensities of the CD11b and GFAP signals in both the mock- and Chandler-infected mice (Fig. 2B, Gdn − and +). Despite the decreased signal intensities, CD11b- and GFAP-positive cells could be distinguished from cells that were negative for those markers. These results suggest that the procedures did not physically affect the cell populations, even though cell marker signals were influenced.

Since the PrP^{Sc} detection method using flow cytometry did not appear to affect the viability and composition of cell populations, we next performed a multiple staining procedure with neural cell markers, microtubule-associated protein 2 (MAP2) for neurons, GFAP for astrocytes, and CD11b for microglia, to analyze the PrP^{Sc} signals in each cell type using flow cytometry. In this analysis, cell bodies positive for 7-AAD and cells positive for CD11b, GFAP, and MAP2 were separated by the cell marker profiles, and the PrP^{Sc} signals from each cell population were analyzed (Fig. 3A). Clear PrP signals were detected in CD11b-positive, GFAP-positive, and MAP2-positive cells, as well as in 7-AAD-positive cell bodies in Chandler-infected samples, and faint or no PrP signals were detected in mock-infected samples (Fig. 3B). This demonstrated the specific detection of PrP^{Sc} in neurons, astrocytes, and microglia from the prion-infected mouse brains by flow cytometry.

PrP^{Sc} is hydrophobic and, thus, more likely to bind to biomolecules nonspecifically. This property could result in false positives in flow cytometric analysis. We needed to exclude the possibility that PrP^{Sc} accumulating in the brain extracellular space was

FIG 1 Legend (Continued)

the signals of the infected and uninfected cells, respectively, stained with isotype control antibodies (P2-284). The table shows mean fluorescence intensity (MFI) of PrP signals detected by each MAb. MFI ratios of ScN2a3-22L to N2a-3 cells are also indicated. (B) Detection of PrP by fluorescence microscopy. N2a-3 and ScN2a-3-22L cells stained with the anti-PrP MAbs for flow cytometry were pelleted, and cell nuclei were counterstained with DAPI. The cells were mounted on a glass slide and analyzed by fluorescence microscopy. The PrP signals are shown as green and the cell nuclei are shown as blue (scale, 10 μm). (C) Detection of PrP-res by immunoblotting. N2a-3, ScN2a-3-22L, ScN2a-3-Ch, GT1-7, and ScGT1-7-22L cells were harvested with collagenase. The cell lysates were subjected to immunoblotting after PK treatment. (D) Flow cytometric detection of PrP^{Sc}. The cells harvested with collagenase were subjected to PrP^{Sc}-specific staining with MAb 132. The histograms show signals of PrP in N2a-3 (blue line) and ScN2a3-22L (red line) cells, PrP signals in N2a-3 (blue line) and ScN2a-3-Ch (orange line) cells, and PrP signals in GT1-7 (blue line) and ScGT1-7-22L (purple line) cells. The black lines and black dashed lines in the histograms show the signals of the isotype control antibody.
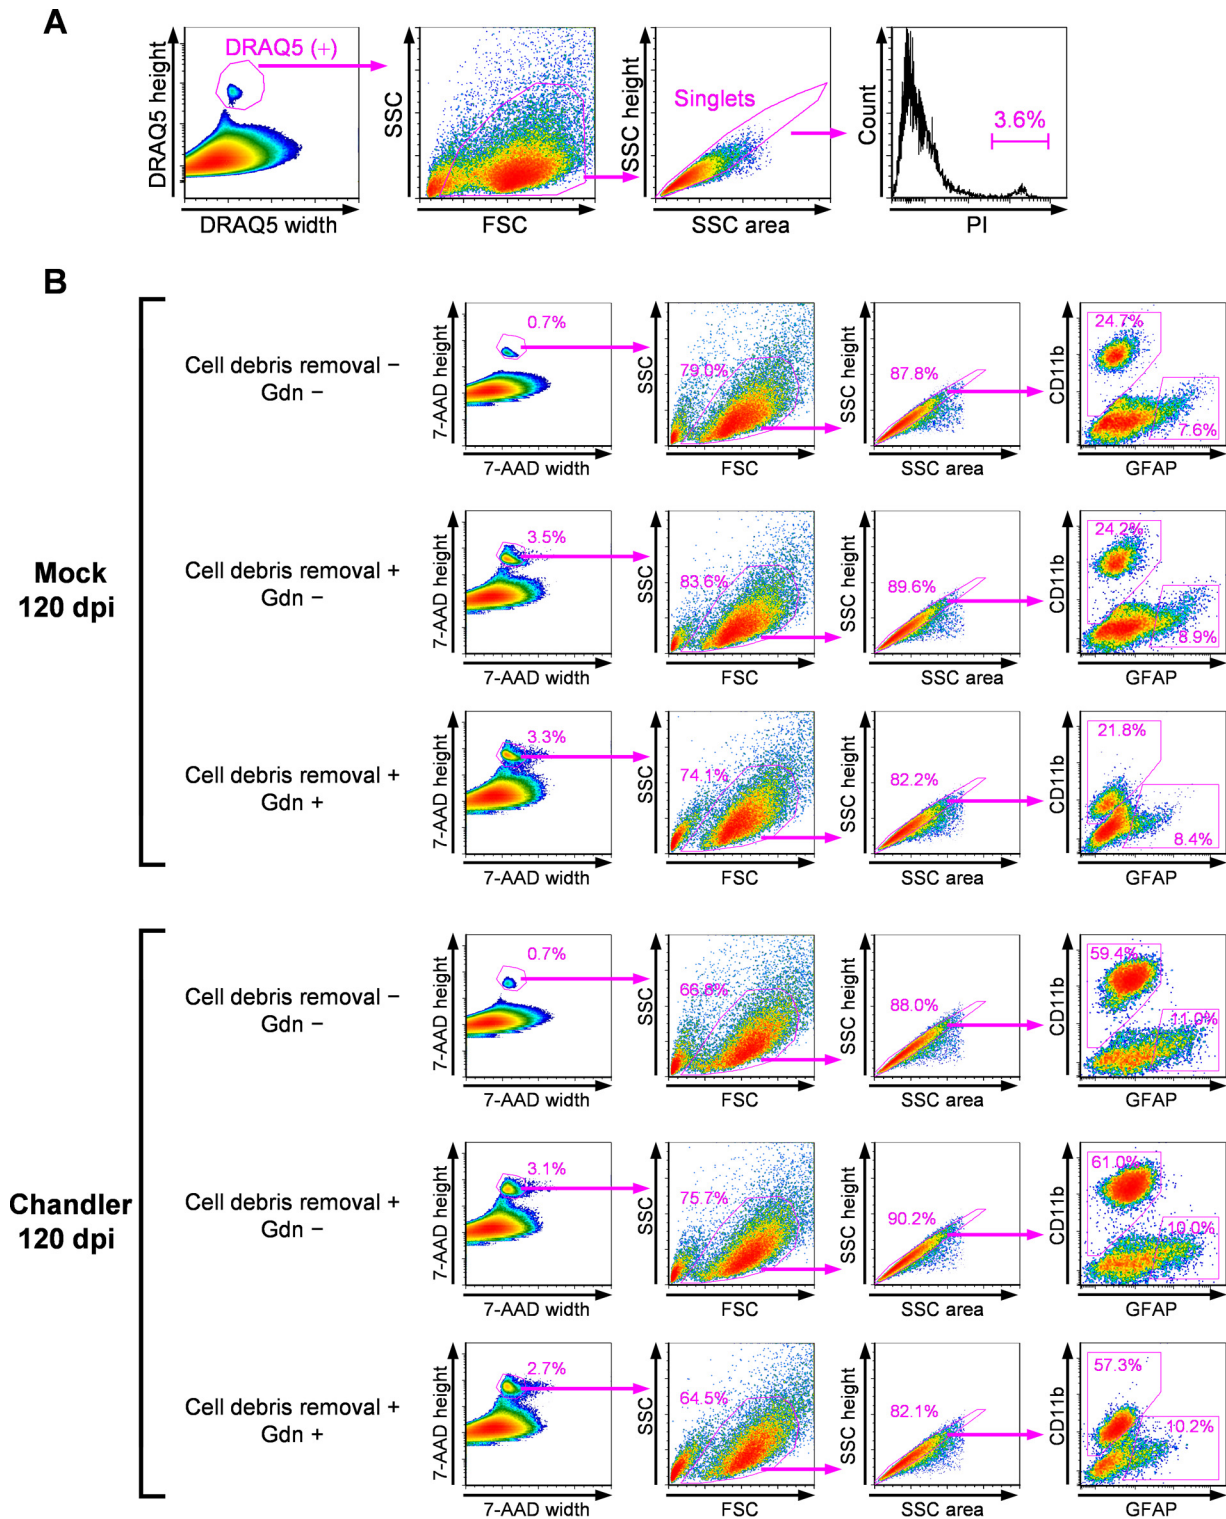

FIG 2 Method for flow cytometric analysis for neural cells from mouse brains. (A) Cell viability. Mock-infected mouse brain at 120 dpi was dissociated with a papain-based enzyme and mechanical trituration. The cell nuclei were counterstained with DRAQ5, and the dead cells were labeled with PI. Cell bodies positive for DRAQ5 were gated to remove cell debris (far left), and then the single events (singlets) were gated based on the profiles of FSC and SSC (second from the left) and the profiles of SSC area and SSC height (third from the left). The rightmost histogram shows PI signals. The percentage of PI-positive cells is indicated in the histogram. (B) Effects of cell debris removal by density gradient centrifugation and GdnSCN treatment on cell marker signals. Cell suspensions prepared from Chandler strain-infected mouse brains and mock-infected mouse brains at 120 dpi were fixed with 4% PFA. Cell debris was removed by density gradient centrifugation (cell debris removal +), or this step was omitted (cell debris removal −). The cells were subjected to GFAP and CD11b labeling and then fixed again with 4% PFA. The cells were treated with 2.5 M GdnSCN (Gdn +) or left untreated (Gdn −). Immediately before flow cytometric analysis, cell nuclei were
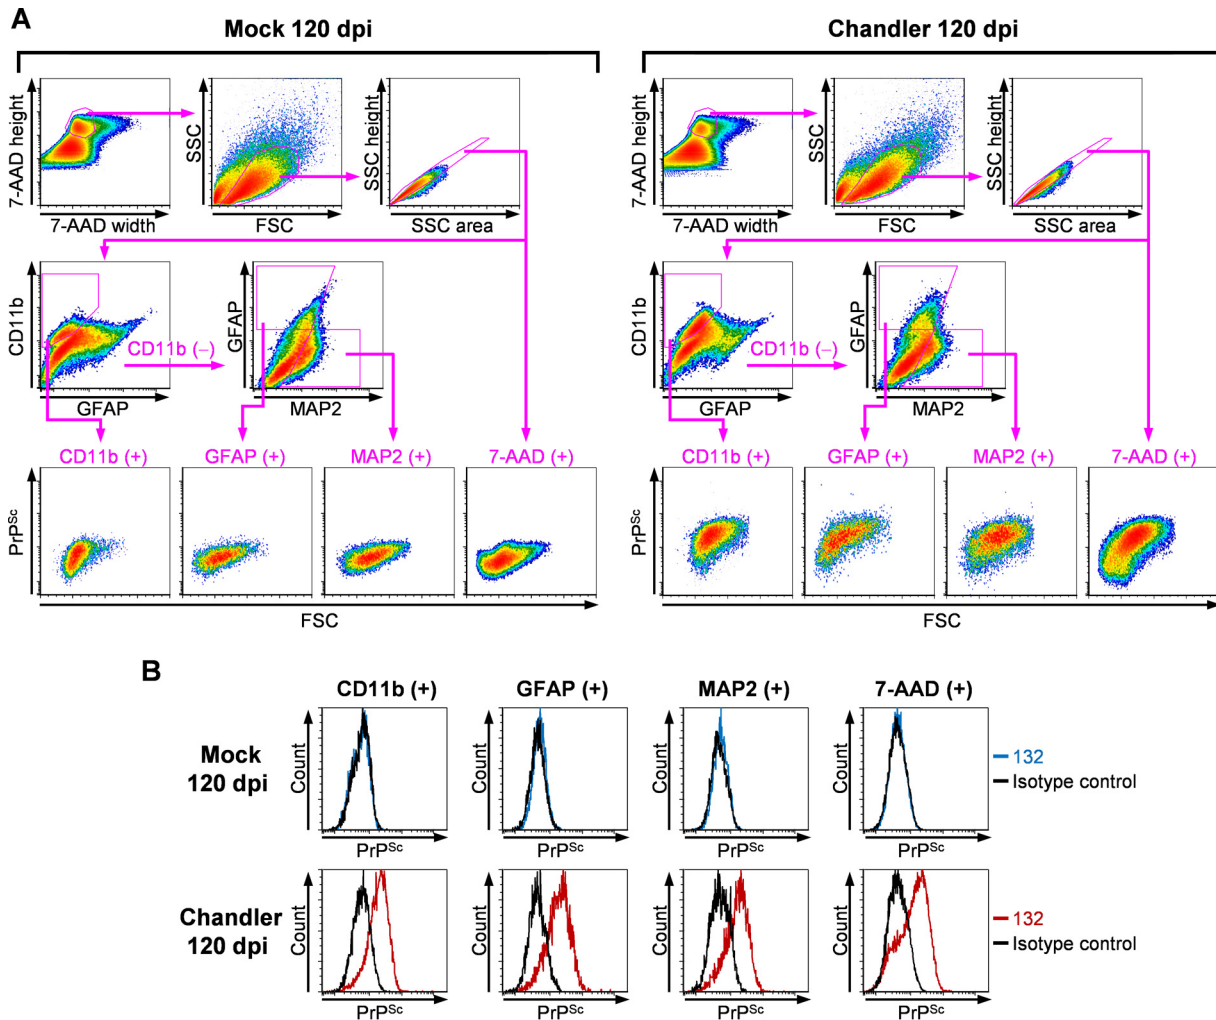

FIG 3 Flow cytometric detection of PrP^Sc in neurons, astrocytes, and microglia from prion-infected mouse brains. (A) Gating strategies for flow cytometric analysis. Cell suspensions were prepared from the mock-infected mouse brains (left) and Chandler strain-infected mouse brains (right) at 120 dpi. The cell suspensions were subjected to the staining of CD11b, GFAP, MAP2, and PrP^Sc; cell nuclei were stained with 7-AAD. For flow cytometric analysis, single-event gating was performed as shown in Fig. 2B. The single events were separated into CD11b-positive and CD11b-negative cell populations based on the profile of the CD11b signals. The GFAP-positive and MAP2-positive cell populations were gated based on the profiles of the MAP2 and GFAP signals of the CD11b-negative cell populations. PrP^Sc signals were analyzed in CD11b-positive, GFAP-positive, MAP2-positive, and 7-AAD-positive cell populations. The sequential gating strategy is shown by the magenta-colored polygonal boxes and arrows. (B) PrP^Sc signals in each cell population. The histograms show the PrP^Sc signals of CD11b-positive, GFAP-positive, MAP2-positive, and 7-AAD-positive cell populations. The blue and red lines show PrP^Sc signals in mock-infected samples (top column) and Chandler strain-infected samples (bottom column), respectively. The black lines show the signals labeled with isotype control antibody.

binding to cells during sample preparation, particularly during the formalin fixation step, thereby resulting in PrP^Sc-positive signals. Therefore, we mixed the brain of the Chandler-infected mouse at 145 dpi (terminal stage of the infection) with the brain of an uninfected ROSA26-enhanced green fluorescent protein (EGFP) mouse that ubiquitously expressed EGFP in many cell types (35), and we prepared cell suspensions from this mixture. We performed the entire procedure for the PrP^Sc-specific staining, including the fixation step (Fig. 4). If PrP^Sc binding to any cell types was occurring during sample preparation and staining, the PrP^Sc could be detected in the EGFP-positive cells. However, PrP^Sc signals were hardly detected in EGFP-positive cells but were clearly

FIG 2 Legend (Continued)

counterstained with 7-AAD. In the analysis, 7-AAD-positive cell bodies were gated (far left), and single events were gated based on the profiles of FSC and SSC (second from the left) and the profiles of SSC area and SSC height (third from the left). The rightmost cytograms show GFAP and CD11b signals. Percentages of the gated cell populations against the parent populations are indicated.
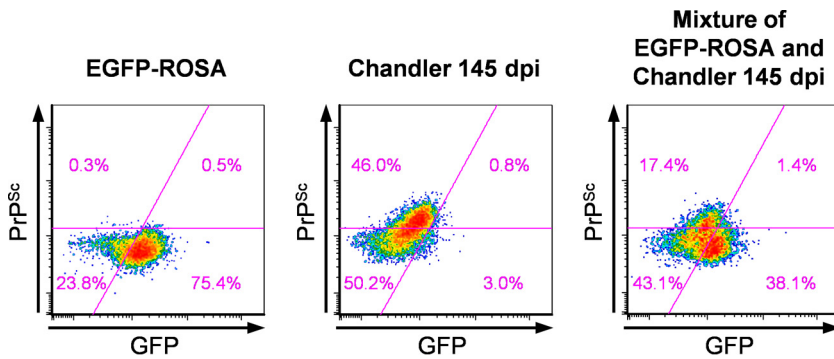

FIG 4 Extracellular PrP^Sc does not affect PrP^Sc detection. Cell suspensions were prepared at 145 dpi from the left brain hemisphere from an uninfected ROSA26-EGFP reporter mouse (left), from the left brain hemisphere from a Chandler strain-infected mouse (center), and from a mixture of the right brain hemispheres from ROSA26-EGFP and Chandler-infected mice (right). The cell suspensions were subjected to GFP staining with anti-GFP antibodies and BV421-conjugated secondary antibodies. After fixation, the cells subsequently were subjected to PrP^Sc staining with MAb 132-Af647. The cytograms show GFP and PrP^Sc signals. The magenta lines represent the threshold levels for GFP and PrP^Sc. Percentages of each population are indicated in quadrants in the cytograms.

detected in EGFP-negative cells from the mixture of the infected and uninfected mouse brains. This result indicates that the detection of PrP^Sc signals was not attributed to the artifactual binding of PrP^Sc to cells but instead reflects the presence of PrP^Sc in cells in the brain.

We next analyzed the kinetics of the proportions of PrP^Sc-positive cells both for neurons and glial cells. Originally, PrP^Sc was detected at 60 dpi in MAP2-positive, GFAP-positive, and CD11b-positive cells (Fig. 5, 60 dpi). In MAP2-positive neurons, 19.2% of cells were already positive for PrP^Sc at 60 dpi, and the percentages increased with time; 80.8% of cells were positive for PrP^Sc at the terminal stage of the disease (at 145 dpi) (Fig. 5, MAP2 +). Surprisingly, percentages of PrP^Sc-positive astrocytes and microglia were also high (Fig. 5, GFAP + and CD11b +). In GFAP-positive astrocytes, 27.0% of cells were positive for PrP^Sc at 60 dpi, and more than 90% of cells were positive

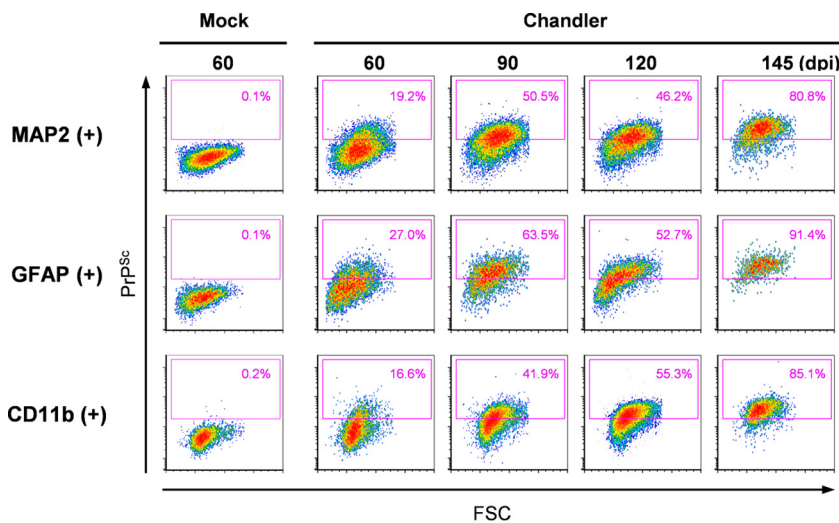

FIG 5 Kinetics of PrP^Sc-positive neurons, astrocytes, and microglia from Chandler-infected mouse brains. Cell suspensions prepared from the brains of Chandler-infected mice at 60, 90, 120, and 145 dpi and from the brains of mock-infected mice at 60 dpi were subjected to flow cytometric analysis for CD11b, GFAP, MAP2, and PrP^Sc. Representative data from two independent experiments are shown. Gating strategies are shown in Fig. 3. The panels show the cytograms of FSC and PrP^Sc signals of MAP2-positive (top), GFAP-positive (middle), and CD11b-positive (bottom) cells. PrP^Sc-positive cell populations are shown in magenta boxes in the cytograms. The threshold level of PrP^Sc is the same in all samples. Percentages of PrP^Sc-positive cells are indicated in the cytograms.
FIG 6 Detection of PrP^{Sc} in neurons, astrocytes, and microglia in a frozen section. The frozen brain section of the Chandler-infected mouse at 60 dpi was subjected to multiple staining of CD11b, GFAP, NeuN, and PrP^{Sc}. The images of each cell marker (magenta) and PrP^{Sc} (green) are shown. The top image is a merged image of NeuN and PrP^{Sc} on the coronal section containing cerebellum and pons (scale, 1 mm). The magnified image of the medial vestibular nucleus (a) and the spinal trigeminal nucleus (b) indicated by white boxes in the top image are shown below (scale, 10 μm). The panel shows merged images of GFAP and PrP^{Sc} (far left), CD11b and PrP^{Sc} (second from the left), and NeuN and PrP^{Sc} (second from the right); a single image of PrP^{Sc} is on the far right. The bottom panel shows increased magnifications of the boxed regions in the spinal trigeminal nucleus images. Colocalization of PrP^{Sc} and each individual cell marker is shown with arrowheads.

for PrP^{Sc} at 145 dpi. The increase in PrP^{Sc}-positive microglia (CD11b-positive cells) was similar to that in MAP2-positive neurons: 16.6% to 85.1% from 60 to 145 dpi. These data suggest that PrP^{Sc} is present not only in neurons but also in astrocytes and microglia from the early to terminal stages of infection. To confirm the presence of PrP^{Sc} in these cells at the early stages of infection (60 dpi), we used multiple stains for PrP^{Sc}, GFAP, CD11b, and a neuronal marker, NeuN, on frozen sections of Chandler-infected mouse brain (Fig. 6). Although most of the PrP^{Sc} signals were distributed away from the signals

of GFAP, CD11b, and NeuN (Fig. 6, representative image at medial vestibular nucleus), a portion of the PrP^{Sc} signals was colocalized either with GFAP, CD11b, or NeuN (Fig. 6, representative image at spinal trigeminal nucleus, arrowheads). This finding is consistent with the detection of PrP^{Sc} in astrocytes and microglia, as well as in neurons, using flow cytometry.

Isolation of PrP^{Sc}-positive cells from prion-infected mouse brain by fluorescence-activated cell sorting. We attempted to apply the flow cytometric analysis of PrP^{Sc} to isolation of PrP^{Sc}-positive neurons and glial cells by fluorescence-activated cell sorting (FACS). From the brain of mouse infected with the Chandler strain at 60 dpi, cells were isolated that were simultaneously double positive for CD11b and PrP^{Sc}, double positive for GFAP and PrP^{Sc}, double positive for MAP2 and PrP^{Sc}, and positive for MAP2 but negative for PrP^{Sc}. As a negative control for the detection of PrP^{Sc}, CD11b-, GFAP-, and MAP2-positive cells were isolated from mock-infected mouse brain. Isolated cells were stained for βIII-tubulin to label neurons again and then analyzed by fluorescence microscopy. High-intensity granular stains specific for PrP^{Sc} were observed in cells that were sorted as PrP^{Sc}-positive and CD11b-, GFAP-, or MAP2-positive fractions. On the contrary, the granular PrP^{Sc} stains were hardly observed in cells that were sorted as a PrP^{Sc}-negative but MAP2-positive fraction from the brain of Chandler-infected mice or in cells from the brain of mock-infected mice (Fig. 7). These results demonstrate the utility of flow cytometric detection of PrP^{Sc} for isolating PrP^{Sc}-positive neurons and glial cells by FACS.

DISCUSSION

Detection of PrP^{Sc} by flow cytometry. Despite a great need for a detailed analysis of PrP^{Sc}-positive neurons and glial cells, methods available for cell type-specific PrP^{Sc} analyses have been limited to microscopic observation thus far. In the present study, we showed PrP^{Sc} detection by flow cytometric analysis in neurons and glial cells using MAb 132 with high throughput and improved quantitative performance.

The immunolabeling of PrP^{Sc} using anti-PrP antibodies is the preferred method for the detection of PrP^{Sc}-positive cells. However, most of the antibodies against the PrP molecule cannot distinguish PrP^{Sc} from PrP^C because they have the same primary structure. Some researchers have reported flow cytometric analysis using PrP^{Sc}-specific antibodies that can immunoprecipitate PrP^{Sc} selectively (36, 37). Paramithiotis et al. showed that PrP^{Sc}-specific signals labeled with MAb 9A4 were detected in dendritic cells isolated from lymph node of scrapie-infected sheep but not in those of uninfected sheep (36). Previously, we tried to detect PrP^{Sc} in prion-infected cells by flow cytometry using PrP^{Sc}-specific antibodies MAb 6H10 (38), 8D5, and 6A12 (39), but our attempts were unsuccessful (data not shown).

There are a few reports on flow cytometric analysis of cells that are positive for misfolded proteins (25, 26, 40, 41). In those reports, cells with misfolded proteins were distinguished from normal cells based on the aggregation or mislocalization of misfolded proteins. For example, monitoring an increase in the intensity of fluorescent reporter proteins that are fused with a target protein is widely used for detection of cells positive for misfolded proteins, such as the mutant superoxide dismutase-1, polyglutamine-expanded huntingtin, and mutant TAR DNA-binding protein 43 (26, 40, 42). However, in the case of prion protein, expression of PrP^C fused to fluorescent proteins has been reported to disturb the conversion of PrP^C to PrP^{Sc} (43); therefore, this method does not appear to be applicable to the detection of PrP^{Sc}. Ramdzan et al. reported the use of pulse-shape analysis (PulSA) to monitor the translocation of misfolded proteins into abnormal cellular puncta by flow cytometry (26). The PulSA method utilizes pulse width and height information of fluorescent signals to discriminate differences in the intracellular localization of signals. Therefore, the availability of this method depends on the change in the intracellular localization of signals between misfolded proteins and normal proteins. We previously reported that PrP^{Sc} was distributed widely to intracellular compartments, including early, late, and recycling endosomes, lysosomes, and perinuclear Golgi regions, as well as plasma membrane, in
FIG 7 Fluorescence-activated cell sorting of PrP^{Sc}-positive cells. Cell suspensions equivalent to one-fifth of a brain of a Chandler-infected mouse at 60 dpi and that of a mock-infected mouse at 60 dpi were subjected to multiple staining of CD11b, GFAP, MAP2, and PrP^{Sc}. Approximately 15,000 CD11b-positive cells, 8,500 GFAP-positive cells, and 13,000 MAP2-positive cells were isolated from the mock-infected mouse brain sample. Approximately 500 CD11b- and PrP^{Sc}-positive cells, 900 GFAP- and PrP^{Sc}-positive cells, 800 MAP2- and PrP^{Sc}-positive cells, and 19,000 MAP2-positive and PrP^{Sc}-negative cells were isolated from the Chandler-infected mouse brain sample using a cell sorter. Isolated cells subsequently were subjected to βIII-tubulin staining to label neurons. The panels show representative images of isolated cells. The far left column shows differential interference contrast cell images. The far right column shows the merged images of CD11b (green), GFAP (blue), βIII-tubulin (red), and PrP^{Sc} (white). The individual images of CD11b, GFAP, βIII-tubulin, and PrP^{Sc} are shown on the second to fifth column from the left (scale, 5 μm).

prion-infected cultured cells, while much of the PrP^C localized at the plasma membrane (30, 31). Despite the differences in intracellular localization between PrP^{Sc} and PrP^C, we did not succeed in discriminating between PrP^{Sc}-positive and PrP^{Sc}-negative cells using the PulSA method with anti-PrP antibody labeling (data not shown).

In a previous study, we showed that PrP^{Sc} staining with MAb 132 allowed for the detection of PrP^{Sc} by fluorescence microscopy without specific manipulations of the threshold settings or digestion of PrP^C molecules (31). Here, we showed that discrimination of PrP^{Sc}-positive and PrP^{Sc}-negative cells by flow cytometry could be achieved with PrP^{Sc}-specific staining using MAb 132 after treating fixed cells with GdnSCN (Fig. 1A). Highly intense granular PrP^{Sc} signals in infected cells compared with PrP^C signals in uninfected cells were clearly detected by microscopy using MAb 106, 31C6, and 44B1, just as with MAb 132 (Fig. 1B). However, antibodies other than MAb 132 could not be used to discriminate prion-infected cells from uninfected cells with the flow cytometry method (Fig. 1A). The difference between MAb 132 and other MAbs is a lack of PrP^C signals from uninfected cells (Fig. 1A and B); thus, the lack of PrP^C signals rather than the intense PrP^{Sc} signals is critical for the clear discrimination between PrP^{Sc}-positive cells and PrP^{Sc}-negative cells using the flow cytometry method. This conclusion is consistent with our recent study on the detection of PrP^{Sc} by cell-based enzyme-linked

immunosorbent assay (ELISA); the lack of PrP^C detection is also important for the discrimination of PrP^{Sc} signals from whole-cell cultures (44). Although the precise reason for the absence of PrP^C detection with MAb 132 is not clear currently, that absence is the key factor that enabled the discrimination between PrP^{Sc}-positive and PrP^{Sc}-negative neurons and glial cells in prion-infected mouse brains.

Cell type-specific detection of PrP^{Sc}. In this study, PrP^{Sc} was detected in astrocytes and microglia, as well as in neurons, from prion-infected mouse brains from the early to terminal stages of prion infection using flow cytometry (Fig. 5). For the detection of PrP^{Sc} in neurons and glial cells, cell debris was removed largely, and only the cell bodies positive for nuclear staining were used for the analysis (Fig. 3A). This may raise the technical problem that PrP^{Sc} in neuronal processes is largely excluded from the flow cytometric analysis. Previous reports suggest that PrP^{Sc} is present predominantly in neuropils, which are composed of the processes of neurons and glial cells, unlike neuronal cell bodies (23, 24, 45). Consistent with these reports, a large portion of PrP^{Sc} was distributed separately from the neuronal and glial markers, while a relatively small portion of PrP^{Sc} was detected by IFA in the cell bodies (Fig. 6). Nevertheless, we could detect PrP^{Sc}-positive cells from an early stage of prion infection (Fig. 5), and granular PrP^{Sc} signals were detected clearly by fluorescence microscopy in PrP^{Sc}-positive cells isolated from the prion-infected mouse brain at 60 dpi by FACS (Fig. 7). These results suggest that this flow cytometric detection of PrP^{Sc} is sensitive enough to discriminate between PrP^{Sc}-positive and -negative cells, even if only a small portion of the PrP^{Sc} in cell bodies is analyzed.

We showed that the proportion of PrP^{Sc}-positive neurons, astrocytes, and microglia increased with disease progression (Fig. 5), which may reflect the cell-to-cell spread of PrP^{Sc} in the brain. Previous studies have indicated that when prions are inoculated into peripheral tissues, PrP^{Sc} is transported from the periphery to the CNS and spreads intracerebrally via neuroanatomical pathways (46–48). Even after intracerebral inoculation of prions, PrP^{Sc} appears to spread via neural circuitry within the brain (21). In addition to neuron-to-neuron spread of PrP^{Sc}, recent studies also have suggested the important roles of glial cells in the spread of PrP^{Sc} between neurons and glial cells. Victoria et al. suggested that astrocytes are involved in the spread of PrP^{Sc} between neurons and astrocytes (20), while Zhu et al. suggested that microglia are involved in the clearance of PrP^{Sc} from the brain (22). In the current study, mice were intracerebrally inoculated with prions. Thus, it is possible that neurons, microglia, and astrocytes were exposed to inoculum and got infected independently in the early stage after inoculation. After the inoculation of prions via the peripheral route, prions enter CNS through sympathetic and parasympathetic nerves (49, 50); therefore, the entry port of CNS will be neurons. Thus, the kinetic analysis of PrP^{Sc}-positive cells in brain after the peripheral infection may address the neuron-to-glial cell spread of prions.

In this study, we succeeded in the isolation of PrP^{Sc}-positive neurons and glial cells from prion-infected mouse brain by FACS (Fig. 7). To our knowledge, this is the first study to specifically isolate neurons and glial cells positive for misfolded proteins from the brains of model animals for misfolding diseases, including prion diseases. Our method requires fixation of cells before the PrP^{Sc}-specific staining; thus, it is impossible to isolate viable cells. However, recent RNA-sequencing techniques have enabled transcriptome analysis using fixed and FACS-isolated neural cells (34, 51). The comprehensive analyses, including transcriptome analysis, on PrP^{Sc}-positive neurons and glial cells isolated by our method will allow a better understanding of the pathological changes that occur in neurons, as well as the roles of glial cells in the PrP^{Sc}-associated pathogenesis. Transcriptome analysis experiments specific to PrP^{Sc}-positive neurons currently are under way to clarify neuronal cell responses to prion infection.

MATERIALS AND METHODS

Antibodies. Anti-PrP mouse MAbs 106, 132, 31C6, and 44B1 (52) were used for the detection of PrP by flow cytometry. MAb P2-284, against feline panleukopenia virus, was used as a negative-control antibody (53). The other commercially available primary and secondary antibodies are listed in Table 1. The antibodies were used for flow cytometry and IFA at the dilution rates shown in Table 1. A Zenon

TABLE 1 Sources of commercially available antibodies and the dilution rates for staining

Antibody	Company	Code no.	Dilution
Primary antibodies			
Anti-MAP2 rabbit monoclonal antibody, D5G1	Cell Signaling Technology	8707	1:400 for flow cytometry
Anti-βIII tubulin chicken polyclonal antibodies	Abcam	ab117716	1 μg/ml for immunofluorescence staining
Anti-GFAP rabbit polyclonal antibodies	Dako	D0344	2 μg/ml for flow cytometry
Anti-GFAP chicken polyclonal antibodies	Abcam	ab4674	5.4 μg/ml for immunofluorescence staining
Anti-CD11b rat monoclonal antibody, M1/70	BioLegend	101202	2.5 μg/ml for flow cytometry, 5 μg/ml for immunofluorescence staining
Anti-GFP rabbit polyclonal antibodies	ThermoFisher Scientific	A11122	5 μg/ml for flow cytometry
Alexa Fluor 488-conjugated anti-NeuN rabbit monoclonal antibody, EPR12763	Abcam	ab190195	0.5 μg/ml for immunofluorescence staining
Secondary antibodies			
Horseradish peroxidase-linked sheep F(ab')$_2$ fragment anti-mouse IgG	GE Healthcare	NA9310	1:5,000 for immunoblotting
Alexa Fluor 488-conjugated goat F(ab')$_2$ fragment anti-mouse IgG	ThermoFisher Scientific	A-11017	1 μg/ml for flow cytometry
Alexa Fluor 488-conjugated goat IgG anti-rat IgG	ThermoFisher Scientific	A-11006	2 μg/ml for flow cytometry
Alexa Fluor 555-conjugated goat IgG anti-rat IgG	ThermoFisher Scientific	A-21434	4 μg/ml for immunofluorescence staining
BV421-conjugated donkey IgG anti-rabbit IgG	BioLegend	406410	1:400 for flow cytometry
Alexa Fluor 555-conjugated goat IgG anti-chicken IgG	ThermoFisher Scientific	A-21437	4 μg/ml for immunofluorescence staining
Alexa Fluor 405-conjugated goat IgG anti-chicken IgY	Abcam	ab175675	1 μg/ml for immunofluorescence staining

R-phycoerythrin (PE) rabbit IgG labeling kit (ThermoFisher Scientific) was used for direct staining of rabbit IgG. Alexa Fluor 647-conjugated MAb 132 (132-Af647) and MAb P2-284 (P2-284-Af647) were prepared by the following procedure. Alexa Fluor 647 succinimidyl ester (ThermoFisher Scientific) was reacted with MAb 132 (1 mg/ml) or MAb P2-284 (1 mg/ml) in phosphate-buffered saline (PBS) at a concentration of 50 μM at room temperature (RT) for 60 min. To inactivate the functional group of the succinimidyl ester, 10 volumes of 100 mM glycine in PBS were added to the reaction solutions. Excess reactive dye and glycine were removed by ultrafiltration using Amicon Ultracel-50k Ultra centrifugal filter units (Millipore). The Alexa Fluor-conjugated antibodies were dialyzed against PBS using Slide-A-Lyzer dialysis cassettes (10,000 molecular weight cutoff; ThermoFisher Scientific). The fluorescent dye/protein (F/P) molar ratios were calculated from absorbance at A_{280} and A_{650} for antibodies and Alexa Fluor 647, respectively, according to the manufacturer's instructions. The F/P molar ratios of the antibodies ranged between 1.5 and 2.5. To adsorb antibodies which nonspecifically react to the cells, 400 μg of Alexa Fluor 647-conjugated antibodies was incubated with 2×10^8 N2a-3 cells fixed with 4% paraformaldehyde (PFA) at a concentration of 10 μg/ml in PBS at RT for 2 h. The supernatant was collected after pelleting the cells by centrifugation at 10,000 × g for 10 min. The antibodies were concentrated by ultrafiltration using Amicon Ultracel-50k Ultra centrifugal filter units and stored at 4℃ until use.

Cell culture. The following cell lines were used: N2a-3 cells, a subclone of the mouse neuroblastoma cell line Neuro2a (54); the hypothalamic neuronal cell lines GT1 and GT1-7 (55); N2a-3 cells persistently infected with the Chandler or 22L prion strain (ScN2a-3-Ch or ScN2a-3-22L); and GT1-7 cells persistently infected with the 22L prion strain (ScGT1-7-22L) (31).

Detection of PrP in cultured cells by flow cytometry. Cells cultured in 100-mm dishes for 72 h were harvested by treatment with 0.1% collagenase (Wako) in PBS at RT for 5 min. The cells were pelleted by centrifugation at 300 × g at 4℃ for 3 min and washed with cold PBS. For fixation, the cells were resuspended in 2 ml of 4% PFA in PBS and incubated at RT for 10 min. The fixation was terminated by adding 13 ml of 100 mM glycine in PBS containing 0.1% Tween 20 (PBST), and the samples were immediately centrifuged at 2,000 × g at 4℃ for 10 min. The pellets were resuspended in 10 ml of 100 mM glycine in PBST and incubated for 10 min. After pelleting, the cells either were treated with 1 ml of 5 M GdnSCN at RT for 15 min or remained untreated. The cells were then washed twice with 10 ml of PBST. For blocking, the cells were incubated with PBST containing 5% fetal bovine serum (FBS) at RT for 30 min. The cells were split to V-bottom 96-well plates (ThermoFisher Scientific) at 1×10^5 cells/well and then pelleted by centrifugation. For the primary antibody reaction, the cells were incubated with 180 μl of anti-PrP MAbs (1 μg/ml) in PBST containing 1% FBS (FBS-PBST) at 4℃ overnight. After the primary antibody reaction, the cells were washed three times with 180 μl of PBST. For the secondary antibody reaction, the samples were incubated with 180 μl of Alexa Fluor 488-conjugated anti-mouse IgG F(ab')$_2$ fragments (1 μg/ml) in FBS-PBST at 4℃ for 60 min. After washing the cells with 180 μl of PBST twice and 180 μl of PBS once, the cells were analyzed by a flow cytometer (FACS Verse; equipped with 488-nm and 640-nm lasers; BD Bioscience). Ten thousand events were collected, using a forward scatter threshold of 10,000. Data from Alexa Fluor 488 were collected in pulse height, area, and width parameters. All flow

cytometry data were analyzed with FACSuite software (BD Biosciences) and FCS 4 Express (De Novo Software).

Mice and prion strains. All animal procedures were approved by the Institutional Animal Care and Use Committee of the Graduate School of Veterinary Medicine, Hokkaido University. Four-week-old female Jcl:ICR mice were purchased from CLEA Japan, and all mice were acclimatized for a week prior to use. The mice were intracerebrally inoculated with 20 μl of a 2.5% (wt/vol) brain homogenate from Jcl:ICR mice infected with the mouse-adapted scrapie strain, Chandler. Mice assigned to the mock-infected group were intracerebrally inoculated with 20 μl of a 2.5% (wt/vol) brain homogenate from age-matched uninfected Jcl:ICR mice, as described in the literature (56). ROSA 26-EGFP reporter mice of congenic strain B6.Cg-Tg(Gt(ROSA)26Sor-EGFP)I1Able/J were purchased from Jackson Laboratories and were maintained further by inbreeding.

Preparation of cell suspensions from brains. The mice were perfused with prechilled modified Hanks' balanced salt solution without Ca^{2+} and Mg^{2+} (HBSS) containing KCl (400 mg/liter), KH_2PO_4 (60 mg/liter), $NaHCO_3$ (350 mg/liter), NaCl (8 g/liter), Na_2HPO_4 (48 mg/liter), and D-glucose (1 g/liter). The brains were removed surgically from the mice and cut into small pieces in 5 ml of chilled HBSS. The brain pieces were dissociated enzymatically using the neural tissue dissociation kit (P) (Miltenyi Biotec), which contains papain as a protease, according to the manufacturer's instructions, with some modifications. After removal of HBSS by centrifugation at 300 $\times$ g at 4°C for 5 min, 1,950 μl of enzyme mix 1 was added to the brain pieces, and the samples were incubated for 15 min at 4°C under slow rotation. Thirty microliters of enzyme mix 2 was added, and the samples were incubated for 15 min at 4°C. The samples were gently triturated 10 times using a Pasteur pipette (Iwaki) and incubated for 15 min at 4°C. The samples again were triturated 10 times, transferred into 5 ml of HBSS in new 15-ml tubes, and then allowed to settle on ice for a few minutes. Five milliliters of the supernatants was filtered through 100-μm nylon mesh (BD Falcon) and collected in new tubes. The remaining sediments again were triturated with a Pasteur pipette 10 times, mixed with 5 ml of HBSS, and allowed to settle on ice for a few minutes. The supernatants then were filtered through 100-μm nylon mesh. This process was repeated and the flowthrough was combined. After centrifugation at 300 $\times$ g at 4°C for 10 min, the pellets were resuspended in 10 ml of HBSS. Cell suspensions were used to analyze dead cell populations and PrP^{Sc} by flow cytometry.

Flow cytometric analysis for dead cell populations. Cell suspensions from brains were incubated for 5 min on ice in 200 μl of HBSS containing DRAQ5 (1 μM; Biostatus), a DNA probe that is permeable to living cells, and PI (10 μg/ml), a DNA probe that is not permeable to living cells. The samples were resuspended in 500 μl of chilled HBSS and analyzed by flow cytometer. The PI and DRAQ5 data were collected until the counts of DRAQ5-positive events reached 10,000.

Flow cytometric analysis of PrP^{Sc} in neural cells from prion-infected mouse brain. Cell suspensions were prepared from mouse brains as described above. After pelleting the cell suspensions by centrifugation at 300 $\times$ g at 4°C for 10 min, the pellets were resuspended in 2 ml of 4% PFA and then incubated at 4°C for 10 min. This fixation step was terminated by adding 18 ml of 100 mM glycine in PBST, and the samples were immediately centrifuged at 2,000 $\times$ g at 4°C for 10 min. The pellets were resuspended in 5 ml of 100 mM glycine in PBST and incubated for 10 min. After pelleting, the cell suspensions were stored in 1 ml of PBST containing 40% FBS and 10% dimethyl sulfoxide at -30°C until use.

Before the immunolabeling of neural cell markers, the cells were thawed rapidly at 37°C, and 100 μl of the samples was transferred to new tubes. The cells were pelleted by centrifugation at 2,000 $\times$ g at 4°C for 10 min. For removal of cellular debris by density gradient centrifugation, the cells were resuspended in 300 μl of 15% iodixanol (OptiPrep, Axis-Shield) in PBST, and the cellular debris was floated by centrifugation at 2,000 $\times$ g at 4°C for 10 min. After removal of the floating cellular debris, this step was repeated once more. To block nonspecific binding of primary antibodies to cells, the cells were incubated with 180 μl of PBST containing mouse immunoglobulin G1, MAb P2-284 (10 μg/ml), and 5% FBS at 4°C for over 30 min. For staining of astrocytes and microglia, cells were incubated at 4°C overnight in 180 μl of primary antibody solution containing anti-GFAP rabbit polyclonal antibodies and anti-CD11b rat MAb in FBS-PBST. After the primary antibody reaction, cells were washed three times with 200 μl of PBST. The cells then were incubated at 4°C for 60 min in 180 μl of secondary antibody solution containing BV421-conjugated anti-rabbit IgG- and Alexa Fluor 488-conjugated anti-rat IgG. The cells were washed three times with PBST and fixed again with 100 μl of 4% PFA at 4°C for 10 min. The PFA was inactivated by adding 900 μl of 100 mM glycine in PBST following incubation with fresh 100 mM glycine for 10 min.

For PrP^{Sc}-specific staining, fixed cells were treated with 100 μl of 2.5 M GdnSCN at RT for 15 min. The GdnSCN was diluted by adding 900 μl of PBST, and the cells were pelleted. After washing with 180 μl of PBST, the cells were incubated at 4°C overnight in 180 μl of antibody solution containing MAb 132-Af647 (2 μg/ml) and Zenon-R-PE-conjugated anti-MAP2 antibodies in FBS-PBST for staining PrP^{Sc} and neurons. After two PBST washes, cells were washed once more with PBS. Cells then were resuspended in 100 μl of PBS containing 2.5 ng/ml 7-AAD (Beckman Coulter) for counter staining. The cells were resuspended in 500 μl of PBS and analyzed by a cell sorter (FACS Aria II equipped with 405-nm, 488-nm, and 640-nm lasers; BD Bioscience). The data from BV421, Alexa Fluor 488, R-PE, 7-AAD, and Alexa Fluor 647 were collected in pulse height, area, and width parameters until the counts of 7-AAD-positive events reached 50,000. All flow cytometry data were analyzed with FACS Diva software (BD Biosciences) and FCS 4 Express.

The threshold levels of CD11b and MAP2 were set using negative-control samples that were prepared with isotype control antibodies instead of the primary antibodies for CD11b and MAP2. The threshold level of GFAP was set as described in the literature (28, 34). The threshold level of PrP^{Sc} was

set as the mean MAb 132-Af647 signals from 7-AAD-positive cell populations in mock-infected samples, plus 3-fold to 4-fold of the value of standard deviations.

FACS of PrP^{Sc}-positive cells. Cell sorting was performed using a FACS Aria II equipped with an 85-μm nozzle. The PrP^{Sc}-positive cell populations were determined by setting the gate over the threshold levels of PrP^{Sc}, as described above. The PrP^{Sc}-negative cell populations were determined by setting the gate under the threshold levels of PrP^{Sc} so that the bottom 90% of cells in mock-infected samples could be included. For microscopic observations of sorted cells, the collected cells were pelleted and incubated in 50 μl of anti-βIII tubulin chicken antibodies in FBS-PBST at 4°C overnight to label neurons. The cells were washed three times with PBST and incubated with 50 μl of Alexa Fluor 555-conjugated anti-chicken secondary antibodies in FBS-PBST at 4°C for 90 min. After washing three times with PBST, the cells were dried on a 15-well multitest slide (MP Biomedicals) and then mounted with ProLong Gold antifade reagent (ThermoFisher Scientific). The fluorescent images of the samples were acquired using laser scanning confocal microscopy (LSM 700; Zeiss).

Immunoblotting. Immunoblot detection of PrP-res was performed as previously described (54).

IFA. The immunofluorescence staining of frozen sections was performed by a method described previously (29), with some modifications. Briefly, the brains were embedded in OCT compound (Sakura Finetek, Japan) and were cut at a thickness of 10 μm. The sections were fixed with 4% PFA for 10 min at RT. The sections were treated with 100 mM glycine in PBS at RT for 10 min and then incubated with blocking solution containing mouse IgG MAb P2-284 (10 μg/ml) and 5% FBS in PBS at RT for over 30 min. The sections then were incubated at 4°C overnight with anti-CD11b rat MAb in PBS containing 1% FBS (FBS-PBS). For the secondary antibody reaction, the sections were incubated at 4°C for 1 h with Alexa Fluor 488-conjugated anti-rat IgG in FBS-PBS. The sections were fixed again with 4% PFA at RT for 15 min and then treated with 2.5 M GdnSCN at RT for 15 min. After incubation with the blocking solution, the sections were incubated at 4°C overnight with MAb 132-Af647 (2 μg/ml), anti-GFAP chicken antibodies, and Alexa Fluor 488-conjugated anti-NeuN rabbit MAb in FBS-PBS. For the secondary antibody reaction, the sections were incubated at 4°C for 1 h with Alexa Fluor 405-conjugated anti-chicken antibodies in FBS-PBS. Finally, the sections were mounted with ProLong Gold antifade reagent. The fluorescent images were acquired using LSM700 and analyzed with ZEN software (Zeiss), as previously described (57, 58).
