Abstract

Background—Hyperammonemia has been associated with intracranial hypertension and mortality in patients with acute liver failure (ALF). We evaluated the effect of renal replacement therapy (RRT) on serum ammonia level and outcomes in ALF.

Methods—Multicenter cohort study of consecutive ALF patients from the United States ALF Study Group registry between 01/1998–12/2016. Firstly, we studied the association of ammonia with hepatic encephalopathy (HE) and 21-day transplant-free survival (TFS) (n=1186). Secondly, we studied the effect of RRT on ammonia for the first 3 days post study admission (n=340) and on 21-day TFS (n=1186).

JCO: Critically revised the manuscript for important intellectual content.

CJK: Conceived the idea of the study, assisted in development of study design and interpretation of data, critically revised the final manuscript for important intellectual content.

Results—Higher admission (n=1186) median ammonia level was associated with grade 3–4 HE (116 vs. 83 μ mol/l) and mortality at day 21 due to neurological (181 vs. 90 μ mol/l) and all causes (114 vs. 83 μ mol/l; P<0.001 for all). Amongst 340 patients with serial ammonia levels, 61 (18%) were on continuous RRT (CRRT), 59 (17%) were on intermittent RRT (IRRT), and 220 (65%) received no RRT for the first 2 days. From days 1 to 3, median ammonia decreased by 38%, 23%, and 19% with CRRT, IRRT, and no RRT, respectively. Comparing to no RRT use, while ammonia reduction with CRRT was significant (P=0.007), with IRRT it was not (P=0.75). After adjusting for year of enrollment, age, etiology, and disease severity, while CRRT (odds ratio [OR], 0.47 [95% confidence interval (CI), 0.26–0.82]) was associated with reduction in 21-day transplant-free all-cause mortality, IRRT (OR, 1.68 [95% CI, 1.04–2.72]) was associated with an increase.

Conclusions—In a large cohort of ALF patients, hyperammonemia was associated with high grade HE and worse 21-day TFS. CRRT was associated with a reduction in serum ammonia level and improvement of 21-day TFS.

Keywords

ammonia; dialysis; liver failure; intracranial hypertension

INTRODUCTION

In acute liver failure (ALF), hepatocyte loss results in reduced ammonia detoxification and hyperammonemia, both through reductions in urea cycle (conversion to urea) and glutamine metabolism. With the frequent coexistent acute kidney injury in ALF, reduced renal ammonia excretion further worsens hyperammonemia [1].

In ALF, hyperammonemia has been associated with hepatic encephalopathy (HE), cerebral edema, intracranial hypertension, and mortality from cerebral herniation [2,3]. The mechanisms by which ammonia causes this neurological dysfunction are still not fully understood. Whether by direct effect or after metabolization to glutamine in the astrocytes, ammonia may contribute to local altered neurotransmitter action, impaired mitochondrial function, and increased oxidative stress, which may lead to downstream astrocytic swelling and cerebral edema [4,5].

In ALF, current ammonia lowering strategies rely mainly on supportive treatment for organ failures [6,7]. However, the use of extracorporeal devices has been proposed to reduce serum ammonia level [8,9]. Recently, in a small cohort study, patients with acute or chronic liver dysfunction and hyperammonemia on renal replacement therapy (RRT) for 24 hours showed a significant reduction in serum ammonia level [10].

To date, no formal study has evaluated RRT effect on serum ammonia level in patients with ALF. In this context, we hypothesized that RRT use would significantly reduce serum ammonia level in comparison to no RRT support. Therefore, we aimed to: determine the association of serum ammonia level and patients' clinical outcomes; evaluate the effect of RRT on serum ammonia level throughout a 3-day period; and assess the effect of RRT on patients' survival.

METHODS

Design, setting, and participants

We performed a retrospective cohort study of patients with ALF enrolled in the United States ALF Study Group (US-ALFSG) prospective registry between January 1998 and August 2016. Patients not fulfilling criteria for ALF (see operational definitions) or with lack of data on serum ammonia level or RRT status at study admission were initially excluded (Supplementary files: Figure 1; original cohort: n=1186). For the analysis of ammonia dynamics between days 1 and 3 post study admission, patients lacking data on serum ammonia level or RRT status for either of these days were excluded (n=340). Within this subset of patients, a sub-analysis was performed following exclusion of the 16 patients enrolled as well in the US-ALFSG ‘STOP-ALF’ trial designed to determine safety and tolerability of ornithine phenylacetate (OPA) a putative ammonia lowering agent, since the use of OPA might confound the results.

The study’s protocol has been approved by the institutional review board or health research ethics board at all enrolling sites (tertiary liver transplantation referral centers) within the US-ALFSG (see acknowledgments). Informed consent was obtained from next of kin for all enrolled patients as they were unable to provide it on their own due to HE. All research procedures were conducted according to the principles of the Declaration of Helsinki [11].

Operational definitions

ALF was defined using the following criteria: a) HE of any degree, b) INR ≥ 1.5 , c) acute illness onset <26 weeks, and d) no evidence of cirrhosis [6]. Given the reported similar clinical impact, we considered both arterial (n=509 at study admission) and venous (n=677 at study admission) ammonia levels [12]. RRT included intermittent (IRRT), such as hemodialysis or sustained low-efficiency dialysis, and continuous (CRRT) modalities [13]. To avoid understating IRRT efficiency and facilitate comparisons with CRRT, the analysis of ammonia dynamics between days 1 and 3 post study admission considered RRT use on days 1 and 2 (up to 48 hours). The use of RRT within the US-ALFSG is not protocolized; therefore indications, modality, replacement fluid, anticoagulation, treatment dose, and timings for initiation and suspension of RRT were based on clinical judgment at each enrolling site.

Exposures and endpoints

The US-ALFSG registry data repository (Medical University of South Carolina) contains demographic, clinical, and outcome data. Data were retrieved on the following baseline characteristics of patients with ALF: age, sex, race, etiology, HE (West Haven criteria), organ support requirements (invasive mechanical ventilation [IMV], vasopressors, and RRT), laboratory serum profile (ammonia, INR, bilirubin, alanine aminotransferase, creatinine, potassium, phosphate, pH, lactate), n-acetylcysteine use, and clinical outcomes (21-day post study admission transplant-free survival [TFS], overall survival, and orthotopic liver transplantation [OLT]).

The primary endpoint for this study was the difference in serum ammonia level between days 1 and 3 post study admission. The secondary endpoint was 21-day post study admission TFS.

Based on previous literature, we could expect a reduction of median serum ammonia level of 22% after 24 hours of CRRT [10]. Accordingly, to detect a difference of 15% in median serum ammonia level between RRT and no RRT use, with 90% power and a cutoff for statistical significance of 0.05, we would require a sample with at least 110 patients in each arm [14].

Statistical analysis

Categorical variables were presented as proportions and continuous variables as median and inter-quartile ranges (IQR). For the baseline characteristics, comparisons for independent samples were performed with Chi-square test or Mann-Whitney test. For the serial ammonia analysis, comparisons for related samples were done with Friedman test. For the baseline characteristics and serial ammonia analyses, missing data was 3% and 5%, respectively; therefore no multiple imputations were performed.

The study of associations with 21-day post study admission transplant-free all-cause mortality was done with logistic regression. For multivariate analysis, covariates were initially chosen based on clinical relevance or $P < 0.10$ on univariate comparisons including: year of admission, age, etiology, HE, IMV, vasopressors, RRT, ammonia, bilirubin, creatinine, potassium, phosphate, pH, lactate, and n-acetylcysteine. Final models were derived based on a stepwise backward elimination process. Collinearity was evaluated and avoided where appropriate. Models' performance was assessed by Chi-square test and area under the receiver operating characteristic curve (AUC). All comparisons considered a threshold for statistical significance of 0.05. Statistical analysis was performed using IBM SPSS Statistics, version 20 (IBM Corp, North Castle, NY, US).

RESULTS

Patients' baseline characteristics

A total of 1186 consecutive patients with ALF and complete data on ammonia level and RRT status at study admission were identified within the US-ALFSG registry between January 1998 and August 2016 (Supplementary files: Figure 1).

Median (IQR) age was 39 (29–52) years and 819 patients (69%) were females. Acetaminophen-related ALF occurred in 593 (50%) patients. All etiologies are specified in Supplementary files: Figure 2.

At study admission, 600 (51%) patients developed grade 3–4 HE. IMV, vasopressors, and RRT were required in 632 (56%), 299 (25%), and 314 (26%) patients, respectively. Median (IQR) INR, ammonia, creatinine, and lactate levels were 2.8 (2.1–4.2), 97 (63–157) $\mu\text{mol/l}$, 1.70 (0.90–3.16) mg/dl , and 4.1 (2.4–7.7) mmol/l , respectively. All baseline characteristics of the original cohort are depicted in Table 1.

Association of serum ammonia level with patients' clinical outcomes

In the original cohort, 1051 patients had complete data on both OLT (1169 patients if OLT status only) and survival (1067 patients if survival status only) status at 21 days post study admission. Amongst them, 224 (21%) were transplanted and 493 (60% of non-transplanted patients) survived without OLT at 21 days post study admission (Table 1). The causes of mortality are specified in Supplementary files: Figure 3.

Median ammonia level at study admission was significantly greater for patients with grade 3–4 vs. grade 1–2 HE (116 vs. 83 μ mol/l) or who died from neurological cause vs. all others (181 vs. 90 μ mol/l) or any cause vs. alive (114 vs. 83 μ mol/l) at 21 days post study admission (Table 2: $P < 0.001$ for all comparisons).

The ammonia cutoffs 100 μ mol/l, 150 μ mol/l, and 200 μ mol/l at study admission were associated with 21-day neurological mortality (without OLT) with a sensitivity of 77%, 58%, and 42% respectively, and a specificity of 55%, 76%, and 87%, respectively (AUC of 0.72 [95% confidence interval (CI), 0.65–0.79]).

Association of patients' baseline characteristics with RRT requirement

Patients on RRT at study admission had significantly greater proportions of grade 3–4 HE (71% vs. 43%) and requirement for IMV (81% vs. 43%) and vasopressors (56% vs. 14%; $P < 0.001$ for all comparisons). These patients had also significantly greater admission median ammonia (110 vs. 95 μ mol/l), creatinine (2.80 vs. 1.34mg/dl), phosphate (3.8 vs. 2.8mmol/dl), and lactate (6.3 vs. 3.5mmol/l) levels ($P < 0.001$ for all comparisons). Furthermore, they had significantly lower 21-day post-study admission TFS (47% vs. 65%, $P < 0.001$). Stratification of all baseline characteristics of the original cohort by RRT requirement at study admission is depicted in Table 1.

Patients admitted during the 2007–2016 period were significantly more likely to be on RRT on day 1 than the ones admitted in the 1998–2006 period (62% vs. 38%; $P = 0.005$). At study admission, being on IRRT was significantly more frequent in the 1998–2006 period (48% vs. 52%; $P = 0.027$), while being on CRRT was more common in the 2007–2016 period (83% vs. 17%; $P < 0.001$).

Amongst patients on RRT at study admission ($n = 314$), the ones on CRRT ($n = 119$) had significantly greater proportion of requirement for vasopressors (64% vs. 51%; $P = 0.029$) than the ones on IRRT ($n = 195$). Patients on CRRT had also significantly greater admission median INR (3.2 vs. 2.7; $P = 0.003$) and lower admission median creatinine (2.3 vs. 3.2mg/dl; $P < 0.001$), phosphate (4.2 vs. 3.3mmol/dl; $P = 0.034$), and lactate (6.2 vs. 7.9mmol/l; $P = 0.025$) levels. However, there was no significant difference on admission median ammonia level (133 vs. 102; $P = 0.052$). All baseline characteristics of patients on RRT at study admission stratified by type of RRT (CRRT vs. IRRT) are depicted on Table 1 of Supplementary files.

Serum ammonia dynamics between days 1 and 3 post study admission

A total of 340 patients with ALF and complete data on ammonia level and RRT status between days 1 and 3 post study admission were identified within the US-ALFSG registry between January 1998 and August 2016 (Supplementary files: Figure 1).

Between days 1 and 3 post study admission, a maximum of 63 (19%), 56 (16%), and 221 (65%) patients were on IRRT, CRRT, or no RRT at all at any each day, respectively. During this 3-day period, median (day 1 vs. day 3) ammonia (100 vs. 81 μ mol/l), INR (3.0 vs. 2.0), creatinine (1.50 vs. 1.49mg/dl), lactate (4.2 vs. 2.8mmol/l), and bilirubin (5.3 vs. 7.8mg/dl) levels varied significantly ($P<0.001$ for all day 1 vs. day 2 vs. day 3 comparisons). Patients' RRT status and biochemical changes between days 1 and 3 post study admission are depicted in Table 3.

Between days 1 and 3 post study admission, the reduction of median ammonia level differed with the type of RRT used during days 1 and 2 (Figure 1): 28.1% with any type of RRT (120 patients), 23.4% with IRRT (any of days 1 and 2 but without CRRT – 59 patients), 37.9% with CRRT (any of days 1 and 2 with or without IRRT – 61 patients), and 18.6% without any RRT at all (220 patients). While median ammonia level reduction with CRRT was significantly greater than without RRT use ($P=0.007$), with IRRT it was not ($P=0.75$).

The variations in ammonia dynamics between days 1 and 3 post study admission with each type of RRT stratified by etiology of ALF (acetaminophen vs. other etiologies) are depicted in Supplementary files: Table S2. Ammonia level reduction with CRRT was greater than no RRT use for both etiology subgroups (38.6% vs. 21.6% for acetaminophen and 38.5% vs. 11.3% other etiologies), but did not reach statistical significance probably due to lower number of patients in each treatment arm ($P=0.085$ and $P=0.054$, respectively).

Ammonia dynamics between days 1 and 3 post study admission were similar within the subgroup of patients with ALF following exclusion of the 16 patients included in the US-ALFSG trial on the impact of OPA for HE management in ALF (Supplementary files: Table 3). Therefore, the overall results were not affected by OPA therapy.

Association of RRT with patients' survival

We derived 3 models to better assess the effect of RRT (overall, IRRT or CRRT) on 21-day post-study admission transplant-free all-cause mortality (Table 4). After adjusting for year of admission (2007–2016 vs. 1998–2006), age, etiology (acetaminophen vs. non-acetaminophen), and disease severity (requirement for IMV, vasopressors, INR, creatinine, and ammonia levels), CRRT use on day 1 was significantly associated with lower 21-day post-study admission transplant-free all-cause mortality (adjusted odds ratio [aOR] of 0.47 [95% CI, 0.26–0.82]). Conversely, IRRT use on day 1 was significantly associated with greater 21-day post-study admission transplant-free all-cause mortality (aOR of 1.68 [95% CI, 1.04–2.72]). The performance of all 3 models was good as defined by AUC values greater than 0.80.

DISCUSSION

Key results and comparisons with previous studies

Using a large cohort of patients with ALF, we have shown that the degree of hyperammonemia was significantly associated with worse clinical outcomes, including high grade (3–4) HE and lower 21-day post study admission TFS ($P<0.001$ for both comparisons). These findings are consistent with previous reports suggesting the use of hyperammonemia as a severity marker in ALF [15,16].

Patients with ALF on RRT at study admission had greater disease severity, especially in terms of extra-hepatic organ failures: more patients demonstrated high grade HE and requirement for IMV and vasopressors, as well as greater median ammonia, creatinine, and lactate levels ($P<0.001$ for all comparisons). Furthermore, these patients had lower 21-day post-study admission TFS (47% vs. 65%; $P<0.001$). These findings likely reflect the choice of RRT for patients with the most severe clinical course of ALF, including acute kidney injury and metabolic acidosis, the most common clinical context for RRT initiation [13,17,18].

In addition, RRT use in patients with ALF increased greatly between the 1998–2006 and 2007–2016 periods (38% vs. 62%; $P=0.005$), especially CRRT utilization (17% vs. 83%; $P<0.001$). These findings likely reflect the increasing use of RRT in clinical practice to treat acute kidney injury in general patients, including those with liver dysfunction. Previous studies have shown a significant improvement in survival and renal function recovery with the timely use of RRT, especially in the most severe cases of acute kidney injury [19,20].

We have also found that RRT use on days 1 and 2 post study admission was associated with a trend towards reduced median serum ammonia level between days 1 and 3 post study admission when compared with no RRT utilization (28.1% vs. 18.6%; $P=0.051$). While such a reduction was significant with CRRT (37.9% vs. 18.6%; $P=0.007$), with IRRT it was not (23.4% vs. 18.6%; $P=0.75$).

To the best of our knowledge, this was the first study to provide evidence of CRRT capacity to reduce serum ammonia level in ALF in comparison with IRRT and no RRT use. In a small cohort study including patients with acute or chronic liver dysfunction and hyperammonemia ($n=24$), Slack and colleagues reported an overall reduction of 22% on median serum ammonia level with 24 hours use of CRRT [10]. In our cohort, the overall reduction in median serum ammonia level with CRRT was greater (37.9%). This difference may be partially explained by the type of patients included in our cohort (only ALF) and the longer course of CRRT utilized (up to 48 hours after study admission). Furthermore, other factors have been described to contribute to CRRT efficiency in this context, for example: pH, blood and replacement fluid flow rates, filter surface area and clotting, and treatment interruptions [8,10,21]. Median pH was found to be within normal range in patients with and without RRT at study admission (7.40 vs. 7.43; $P<0.001$), therefore it unlikely affected ammonia dynamics. However, data regarding other such technical aspects of RRT were not recorded in the US-ALFSG registry (see limitations).

Finally, we showed that CRRT use at day 1 was independently associated (after adjusting for year of admission, age, etiology, and disease severity) with lower 21-day post-study admission transplant-free all-cause mortality (aOR of 0.47). Conversely, IRRT was independently associated with higher 21-day post-study admission transplant-free all-cause mortality (aOR of 1.68). To the best of our knowledge, no previous study has demonstrated this kind of an impact of RRT on the outcomes of patients with ALF.

In a study designed to study the impact of high-volume plasma exchange on hospital survival of patients with ALF, Larsen and colleagues reported that median serum ammonia levels decreased significantly more rapidly with high-volume plasma exchange than with standard medical treatment (29.7% vs. 1.5% between days 1 and 3 post study admission) [22]. Furthermore, high-volume plasma exchange significantly improved hospital TFS (58.7% vs. 47.8%). The plasma exchange protocol used in this study consisted of replacing 8–12L of plasma per day (at 1–2L per hour rate) for 3 days using 100% fresh frozen plasma. While this technique may resemble a subtype of IRRT, the composition of the replacement fluid is different from the ones used in regular RRT sessions. Moreover, plasma exchange efficacy may in part be due to a specific dampening effect on the innate immune system response.

Previous studies have evaluated the effect of RRT on hemodynamics in patients with ALF and acute kidney injury. They have shown that, while IRRT use has been associated with a significant reduction in cardiac index and mean arterial pressure and a significant increase in intracranial pressure, CRRT utilization has not [23,24]. Consequently, CRRT was deemed safer than IRRT in patients with ALF and risk of cerebral edema. Therefore, CRRT use in patients with ALF appears to improve hyperammonemia and reduce the risk of cerebral edema and intracranial hypertension while avoiding hemodynamic changes that may exacerbate intracranial pressure.

Using only a specific threshold of serum ammonia to select patients for CRRT in this context might not be enough, given lack of sensitivity observed. Nevertheless, a serum ammonia level 150–200 μ mol/l has been associated with increased risk of cerebral edema and intracranial hypertension [16]. While this study was not designed nor powered to determine a threshold serum ammonia value to stop CRRT, we would advocate for the decision to cease CRRT be based on further clinical data besides serum ammonia level (e.g. serum pH, bicarbonate, and potassium, urine output, fluid balance).

Taking into account pre-existent literature and our findings, we suggest that patients with ALF and hyperammonemia, especially those at greater risk for cerebral edema and intracranial hypertension (e.g., with high grade HE, need for vasopressors or with acute kidney injury), should be considered for CRRT [16, 25].

While serum ammonia modulation with CRRT may impact positively ALF patients' clinical outcomes, this becomes only one more adjunctive therapeutic strategy to control neurological failure. The timely treatment of all organ failures in ICU is of paramount importance and has contributed greatly for the overall improvement of these patients' clinical outcomes over the past decades [7].

Limitations

This study had the following limitations that warrant consideration. Firstly, this was a retrospective cohort and therefore may have been prone to selection bias. However, the large sample size, multicenter character, and the use of data from prospectively enrolled patients meeting entry criteria in the US-ALFSG registry may have helped to minimize the risk of such bias.

Secondly, further details on RRT specifics were not possible to obtain within the US-ALFSG registry. This additional data may have added to the explanation of RRT effect on ammonia dynamics and patients' clinical outcomes in ALF. Nevertheless, currently there is still controversy regarding most technical aspects of RRT use in general patients, including indications, early vs. late initiation, intermittent vs. continuous modes, diffusion vs. convection modes, pre vs. post dilution fluid replacement, high vs. low treatment dose, and stopping rules [13,19]. For example, previous studies have shown that, amongst general critically ill patients, diffusion and convection modes have similar capacity for clearance of small molecules (e.g., urea, creatinine, ammonia, glutamine) [26]. Furthermore, high (>35mL/kg/h) and low (<35mL/kg/h) dose of renal replacement have been reported to have similar effect on mortality and renal function recovery [27]. Even if in specific subgroups of patients, these technical aspects may apply differently, the conclusions of such studies help to strengthen the validity of our results [28].

Despite these limitations, we believe that our findings add to the previous literature on hyperammonemia and cerebral edema management in ALF [6]. To date, this is the largest multicenter study to evaluate the effect of RRT on hyperammonemia in ALF. To further study the use of RRT in this context, clinical trials should be attempted in the near future. However, this may prove to be a difficult task; not only is ALF a rare disease, but also hyperammonemia may be difficult to isolate from classical indications for RRT initiation in the context of acute kidney injury [13,28].

Conclusions

In a large cohort of patients with ALF, hyperammonemia was associated with worse high-grade HE and 21-day post study admission TFS. Furthermore, CRRT was associated with a reduction in serum ammonia level and improved 21-day post-study admission TFS. In ALF, CRRT may be an effective adjunctive therapy to improve hyperammonemia as well as overall clinical outcomes.
