Edited by Gerald W. Hart

Mycobacterium tuberculosis antigen 85 (Ag85) enzymes catalyze the transfer of mycolic acid (MA) from trehalose monomycolate to produce the mycolyl arabinogalactan (mAG) or trehalose dimycolate (TDM). These lipids define the protective mycomembrane of mycobacteria. The current model of substrate binding within the active sites of Ag85s for the production of TDM is not sterically and geometrically feasible; additionally, this model does not account for the production of mAG. Furthermore, this model does not address how Ag85s limit the hydrolysis of the acyl-enzyme intermediate while catalyzing acyl transfer. To inform an updated model, we obtained an Ag85 acyl-enzyme intermediate structure that resembles the mycolated form. Here, we present a 1.45-Å X-ray crystal structure of *M. tuberculosis* Ag85C covalently modified by tetrahydrolipstatin (THL), an esterase inhibitor that suppresses *M. tuberculosis* growth and mimics structural attributes of MAs. The mode of covalent inhibition differs from that observed in the reversible inhibition of the human fatty-acid synthase by THL. Similarities between the Ag85-THL structure and previously determined Ag85C structures suggest that the enzyme undergoes structural changes upon acylation, and positioning of the peptidyl arm of THL limits hydrolysis of the acyl-enzyme adduct. Molecular dynamics simulations of the modeled mycolated-enzyme form corroborate the structural analysis. From these findings, we propose an alternative arrangement of substrates that rectifies issues with the previous model and suggest a direct role for the β-hydroxy of MA in the second half-reaction of Ag85 catalysis. This information affords the visualization of a complete mycolyltransferase catalytic cycle.

Tuberculosis is caused by *Mycobacterium tuberculosis*, a slowly replicating bacillus that primarily afflicts the respiratory system (1). A signature characteristic of *M. tuberculosis* is its complex cell envelope, which includes a unique lipid-rich outer membrane (mycomembrane) that provides superior environmental protection and a formidable barrier for antibiotic uptake (2). *M. tuberculosis* is encapsulated by an inner membrane and a periplasmic region possessing a thick peptidoglycan layer that is covalently linked to the arabinogalactan (AG),[3] which is in turn covalently modified on the 5-hydroxy of the terminal arabinose by an ester-linked mycolic acid (MA) (3). The mycolated AG (mAG) accounts for the majority of the inner leaflet of the mycomembrane, whereas the outer leaflet is composed of various glycolipids, phospholipids, sulfolipids, and mycolated forms of trehalose (trehalose mono- and dimycolate (TMM and TDM, respectively)) (3).

MAs are unique to the *Mycobacterium* genus and consist of two alkyl chains: the shorter α-chain (24–26 carbons) and the longer, variable meromycolate chain capped by a β-hydroxy (48–62 carbons; *cis*- or *trans*-methoxy, *cis*- or *trans*-keto, and *trans*-hydroxy structural forms) (4). Biosynthesis of MAs occurs in the cytoplasm with the penultimate form being a mycolic β-keto ester on the 6-hydroxy of a trehalose molecule. Following reduction of the β-ketone to a β-hydroxy by CmrA, production of TMM is complete, and it is transported to the periplasm by MmpL3 (4). TMM serves as the source of MA required for the production of mAG and TDM by the essential antigen 85 (Ag85) complex (Fig. 1*A*) (4–6).

The Ag85 complex is encoded by the *fbp* genes (*fbpA*, *fbpB*, and *fbpC*) and comprises Ag85A, Ag85B, and Ag85C, three secreted, homologous transesterase enzymes (5). All three enzymes have been shown to be capable of catalyzing the production of TDM and mAG from TMM and respective MA acceptors (5). MA transfer occurs selectively onto the 6′-hydroxy of TMM to yield trehalose 6,6′-dimycolate or the 5-hydroxy of the terminal arabinose to produce mAG (4). Ag85

enzymes are members of the α/β-hydrolase superfamily with the three *M. tuberculosis* Ag85 homologs possessing a sequence similarity greater than 75% and nearly identical substrate-binding sites (7–9). Indeed, the known trehalose-binding site located within the Ag85 active site is identical in all three *M. tuberculosis*-encoded homologs. Ag85s utilize a ping–pong reaction mechanism with a catalytic triad composed of a nucleophilic serine (Ag85C: Ser[124]), histidine base (Ag85C: His[260]), and glutamic acid (Ag85C: Glu[228]) (Fig. 1*B*) (7–9).

Two trehalose-binding sites on Ag85 enzymes have been identified: the secondary site, which is located near the middle of the α9-helix and the base of the α5-helix, and the active site, with the 6-hydroxy pointing toward the nucleophilic serine residue (Fig. 1*C*) (9). On the basis of these observed binding sites, Anderson *et al.* (9) proposed an interfacial mechanism model in which TMM initially binds at the secondary site outside the active site, stimulating a conformational change of the side chain of Phe[232] in Ag85A and -B (Leu[230] in Ag85C) that allows TMM to then enter the active site and undergo nucleophilic attack as the initiating step of the first half-reaction. Following this step, the liberated trehalose molecule transiently resides in the active site until it is released as the product of the first half-reaction. This scheme suggests that, in the acyl-enzyme intermediate form, the α-chain of MA is buried in a hydrophobic hole with the meromycolate chain flipped out away from the enzyme and residing within the mycomembrane (9). The second half-reaction would then proceed upon binding of a second molecule of TMM to the secondary site followed by translocation to the active site (9). TDM is thereby produced following nucleophilic attack on the MA-enzyme intermediate by the second molecule of TMM in the active site (9).

Shortly after the interfacial mechanism model was proposed, an X-ray crystal structure of the octyl thioglucoside in complex with Ag85C was solved, highlighting potential problems with the proposed arrangement of substrates (8). The sugar moiety of octyl thioglucoside sits in the sugar-binding region/pocket of the active site with the non-hydrolyzable thioether linkage located near the nucleophilic serine. The octyl chain resides in a hydrophobic cleft pointing toward the secondary site and the potential hydrophobic hole for the α-chain of MA. The positioning of the octyl chain highlights how sterically hindered the active site would become following acylation of the enzyme, hindering the translocation of the second molecule of TMM from the secondary site to the active site. To decipher potential substrate specificity, a recent study investigated the few non-conserved residues among Ag85 homologs, some of which are near the secondary trehalose site (11). That study suggested that variations in the protein sequence affect the dynamic nature of the α9-helix, resulting in noticeable differences in substrate specificity and negating the relevance of the secondary binding site to catalysis (11).

Mutation and structural studies have shown that a disruption of the hydrogen bond network in the active site results in helical relaxation and loss of enzymatic activity (12). Specifically, when the nucleophilic serine (Ser[124]) was mutated to an alanine, resulting in the loss of a hydrogen bond to the catalytic histidine (His[260]), relaxation in the α9-helix was observed (12). A similar structural shift was observed in the Ag85C-diethyl phosphate

cocrystal structure, which mimics the tetrahedral transition state (7). These mutagenesis and structural studies, paired with the findings of Backus *et al.* (11), suggest a direct relationship between the dynamic movement of the α9-helix and the catalytic cycle (7, 12).

On the basis of the previous studies described above and a detailed analysis of *M. tuberculosis* Ag85 structures determined over nearly two decades, we questioned the accuracy of the current model of substrate arrangements and the interfacial mechanism in Ag85 enzymes. Furthermore, we were intrigued as to how the enzyme limits the hydrolysis of the biologically expensive acyl-enzyme intermediate. To address these topics, we pursued a structure of the elusive mycolated form of the acyl-enzyme intermediate. Due to the insoluble nature of MAs, we used tetrahydrolipstatin (THL), which possesses two alkyl chains and yields a β-hydroxy as a result of nucleophilic attack on the β-lactone ring of THL by the enzyme. Both of these chemical characteristics mimic the core attributes of MAs. *M. tuberculosis* Ag85C was cocrystallized with THL, a covalent lipid esterase inhibitor with a minimum inhibitory concentration of 5 μg/ml against *M. tuberculosis* (13). The resulting X-ray cocrystal structure of Ag85C-THL was solved to 1.45 Å. This structure and subsequent analyses suggest how the enzyme protects the solvent-exposed acyl-enzyme intermediate form and provides a basis for an updated model of substrate binding that directly influences catalysis.
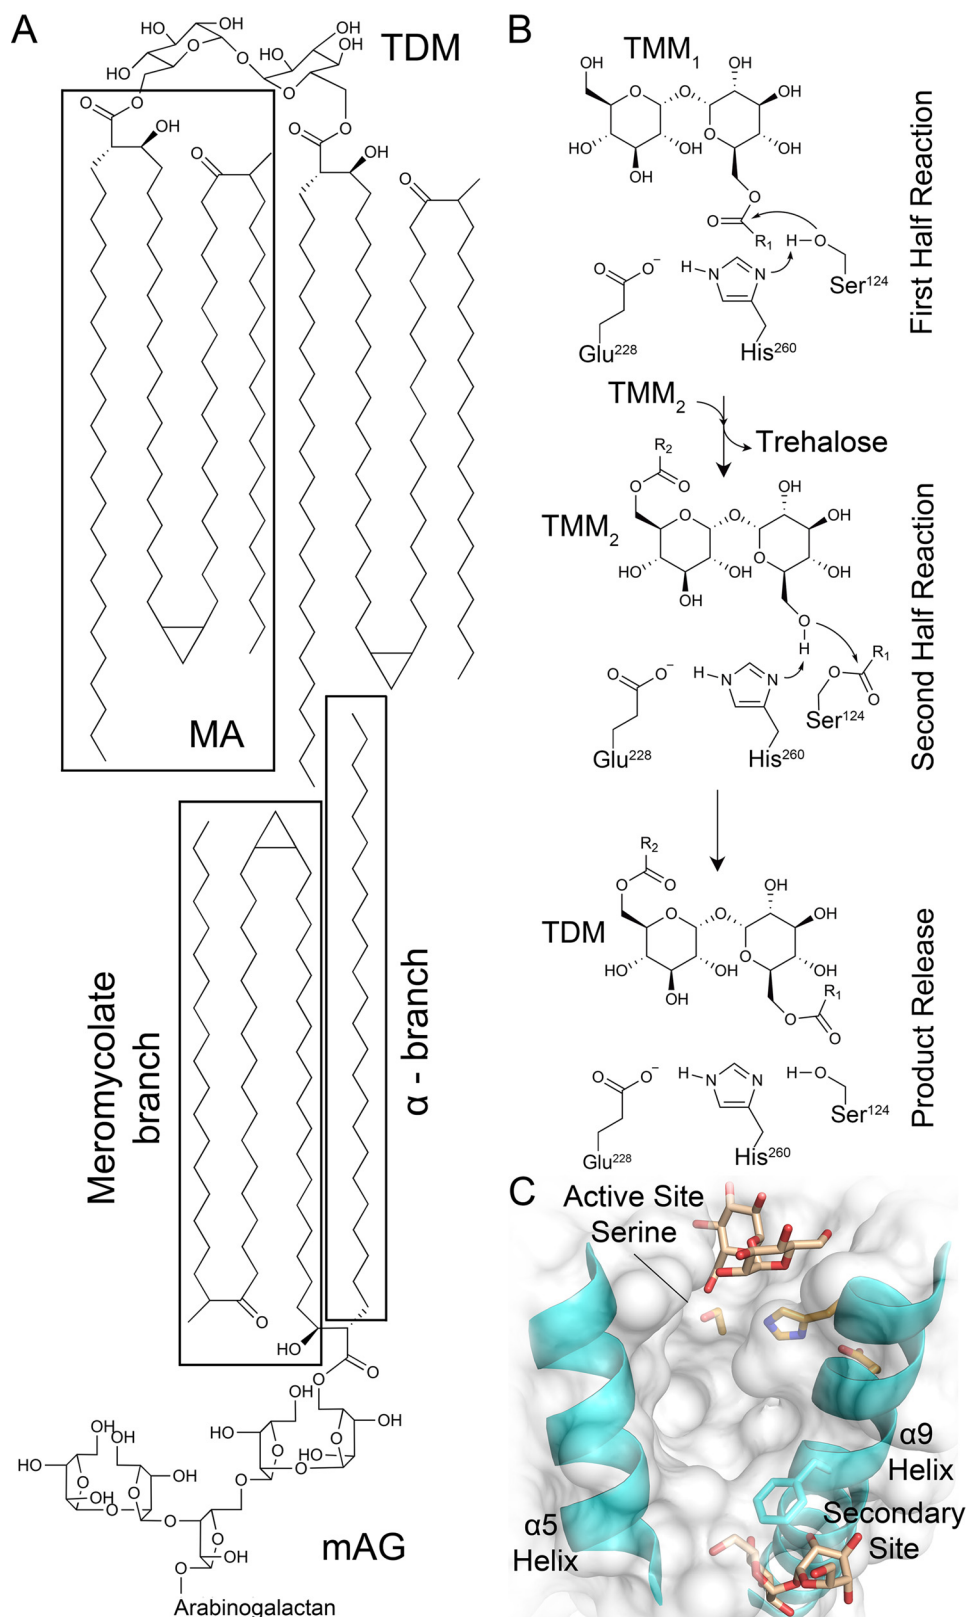

Results

Covalent inhibition by THL

THL is a well known lipid esterase inhibitor that suppresses *M. tuberculosis* growth (13). Covalent inhibition results from nucleophilic attack on the carbonyl center in the β-lactone ring of THL by Ag85s (Fig. 2*A*). To determine the rate of covalent inhibition and thus acylation of the enzyme by THL, k_{inact}/K_I was measured to be $7.9 \pm 1.0 \times 10^{-3}$ μM^{-1} min^{-1} by monitoring the rate of transesterification by Ag85C in the presence of varying concentrations of THL (Fig. 2*B*). Inhibition progress curves are provided in Fig. S1.

Ag85C-THL X-ray crystal structure

M. tuberculosis Ag85C was cocrystallized with THL, resulting in a structure of 1.45-Å resolution (crystallographic and refinement statistics are in Table 1). Continuous difference density was present for all atoms of THL. The $F_o - F_c$ omit map for the THL-modified Ser[124] and $2F_o - F_c$ map for surrounding residues is shown in Fig. 3*A*. Covalent modification of Ser[124] by THL results in an ester linkage between the drug and enzyme and yields the β-hydroxy of THL as a result of ring opening. The carbonyl of that ester linkage points directly toward the identified oxyanion hole of the backbone amides of Met[125] and Leu[40] (Fig. 3*B*) (7). The alkyl chains of THL lie within a hydrophobic cleft extending back toward the secondary trehalose-binding site, which resides below the terminal methyl carbon of the palmitic core chain. The hexanoyl tail approaches the hydrophobic hole; however, it does not extend down into this channel, which is occupied by seven water molecules (Fig. S2*A*). The peptidyl side arm of THL is extended toward the α9-helix, displacing the catalytic His[260]. Additionally, the α9-helix adopts a

relaxed conformation relative to the kinked apo structure, displacing the helix away from the protein core (Fig. S2*B*). Unfortunately, interpretable electron density for residues 216–221, which account for a dynamic loop connecting the α9-helix to the preceding β7-strand, was not present and therefore was not modeled. Two glycerol molecules are present in the trehalose active site location with one hydroxy pointing toward the acyl-enzyme intermediate and the β-hydroxy of THL ($F_o − F_c$ omit map in Fig. 3*A*). Aside from these noted observations, the overall protein fold is identical to that of apoAg85C with the two structural models exhibiting an r.m.s.d. of 0.23 Å (Fig. S2*B*).

Structural analysis of Ag85s with disrupted catalytic triads

In the catalytically active enzyme, the nucleophilic hydroxy of Ser[124] is hydrogen-bonded to the ε-nitrogen of the His[260] imidazole ring, and the δ-nitrogen of His[260] is hydrogen-bonded to Glu[228] (Fig. 4*A*) (7). In this form, the α9-helix is kinked toward the active site with a connecting dynamic loop positioned away from the active site, allowing for substrate

binding (Fig. 4*A*). In structures exhibiting a disrupted catalytic triad, His[260] rotates about both χ_1 and χ_2 to form an interaction with the side chain of Ser[148] (Fig. 4*A*) (7, 12, 14, 15). Disruption of hydrogen bonds with residues of the α9-helix therefore relaxes the helix, allowing the dynamic loop to be positioned over the active site, resulting in the side chain of Leu[217] being oriented between His[260] and the nucleophilic Ser[124] (Fig. 4, *A* and *B*) (12). Residue conservation at position 217 is split between leucine and isoleucine in all mycolyltransferases (Fig. S3*A*). Positioning of the aliphatic side arm of THL is similar to that of Leu[217] (Fig. 4*B*). In both the disrupted catalytic and THL-modified forms, the aliphatic substituents help orient the His[260] side chain such that it maintains a hydrogen bond with Ser[148] and abrogates potential solvent interactions with His[260], decreasing the potential for water activation (Fig. 4*B*).

This repositioning of His[260] by disruption of the catalytic triad results in the formation of a hydrogen bond between the δ-nitrogen of the imidazole ring and the neighboring hydroxy of Ser[148]. Ser[148] and the neighboring Trp[265], which forms a hydrogen bond with Ser[148] through its indole nitrogen, are both highly conserved among all known mycolyltransferases (Fig. S3, *B* and *C*). In every Ag85C structure with disrupted catalytic triads, a similar displacement of His[260] that mimics this acylated form is present (Fig. 4*B*) (7, 12, 14, 15).

WT, S148A, and S148T enzymatic activity

Based on the structural alignments and high sequence conservation, we sought to determine whether Ser[148] plays a direct role in sequestering the catalytic His[260] to limit hydrolysis of the acyl-enzyme intermediate. To investigate potential effects of Ser[148] on enzymatic activity, we mutated Ser[148] to alanine and threonine. Both variants lacked observable transesterase activity but exhibited hydrolase activity at a lower level than that of WT (43.46 ± 3.1 and 25.06 ± 1.4% of observed WT hydrolysis for S148A and S148T, respectively) (Fig. S4).

Molecular dynamics

To investigate the conformational dynamics of the acyl-enzyme intermediate and THL-inhibited forms of Ag85C, we performed conventional molecular dynamics (MD) simulations of four models. Specifically, we simulated Ag85C in complex with THL (Ag85C-THL), MA (Ag85C-MA-His[260]$_{seq}$ and Ag85C-MA-His[260]$_{cat}$), and trehalose with MA (Ag85C-MA-trehalose). The Ag85C-MA models contained two different conformations of His[260], *i.e.* the sequestered position and the catalytic position. In the sequestered position, His[260] is hydrogen-bonded to Ser[148], whereas in the catalytic position, His[260] is hydrogen-bonded to the proximal β-hydroxy of MA (Ag85C-MA-His[260]$_{cat}$). The fourth model (Ag85C-MA-trehalose) is with His[260] in the catalytic position and an acceptor molecule of trehalose in the active site sugar-binding site. The Ag85C-MA-trehalose simulation was conducted to study our proposed substrate-binding model and to gain insights into nucleophilic activation for the second half-reaction. Details on how each of the four MD starting models were generated are given under "Experimental procedures."

Each Ag85C model maintained important active site interactions over the time scale of the simulations (see results below).

**Figure 3. Ag85C-THL structure.** *A*, $F_o - F_c$ likelihood-weighted omit map (*blue*) contoured to 3.0 σ for Ser[124] modified by THL and glycerol molecules in the active site and $2F_o - F_c$ map (*red*) contoured to 1.5 σ for surrounding active site residues. *B*, surface rendering of Ag85C with Ser[124] modified with THL and two glycerol molecules occupying the trehalose-binding portion of the active site.

Figure 4. Observed structural changes between the active and acyl-enzyme intermediate forms. *A*, catalytic triad disruption results in relaxation of the α9-helix with His[260] adopting a sequestered position (*white*, Ag85C-S124A, Protein Data Bank code 4QEK; *cyan*, trehalose-bound Ag85B, Protein Data Bank code 1F0P) (9, 12). *B*, consistent displacement of His[260] results in hydrogen bond formation with Ser[148]. The aliphatic side arm of THL mimics the hydrophobic interactions of the side chain of Leu[217] in the diethyl phosphate–modified Ag85C and S124A mutant structures (*wheat*, Ag85C-THL, Protein Data Bank code 5VNS; *green*, Ag85C-diethyl phosphate, Protein Data Bank code 1DQY; *white*, Ag85C-S124A, Protein Data Bank code 4QEK) (7, 12).

In addition, each model exhibited moderate backbone r.m.s.d. fluctuations (<2.5 Å) of the entire protein throughout the simulations (Fig. S5). Specifically, for Ag85C-THL, His[260] remained sequestered to Ser[148], and the overall complex was found to be stable throughout the simulation. When THL was modeled to mimic the natural substrate, *i.e.* in the Ag85C-MA-His[260]$_{seq}$ model, His[260] remained in the sequestered conformation. His[260] remained within hydrogen-bonding distance of Ser[148] for the entire simulation despite the removal of the pep-

tidyl side arm (Fig. 5, *A* and *C*). When His[260] was positioned in the catalytic orientation, a hydrogen bond between His[260] and the β-hydroxy of MA was present in fewer than 25% of the simulation trajectory, which is substantially more transient than in the Ag85C-MA-His[260]$_{seq}$ model. Specifically, the Ag85C-MA-His[260]$_{seq}$ model maintained a hydrogen bond between His[260] and Ser[148] for 98% of the simulation trajectory (Fig. 5, *B* and *C*). When an acceptor molecule of trehalose was present and His[260] was in the catalytic position (Ag85C-MA-trehalose), His[260] was within a weak-to-moderate hydrogen-bonding distance (N···H distance within 2.5 Å) with either the β-hydroxy of MA or the 6′-hydroxy of trehalose (Fig. 6A). Interestingly, in the presence of trehalose, His[260] did not interact with the solvent through hydrogen bonding but rather alternated between interacting with the β-hydroxy of MA and the 6′-hydroxy of trehalose (Fig. 6B). Therefore, we propose that the binding of the incoming acceptor molecule drives the protein to form an active conformation. Based on the two hydrogen-bonding configurations of His[260] that were observed in the Ag85C-MA-trehalose MD simulation, the second half-reaction could therefore proceed through a direct or indirect activation pathway upon acceptor molecule binding (Fig. 7).

To achieve more thorough phase space sampling and obtain an unbiased representation of thermodynamically accessible conformations in the acyl-enzyme intermediate, we also performed temperature replica-exchange molecular dynamics (T-REMD) simulations on the Ag85C-MA-His[260]$_{cat}$ model. T-REMD is an enhanced sampling method that affords a more extensive and efficient exploration of phase space than conventional MD simulations (16–18). For the T-REMD simulations of Ag85C-MA-His[260]$_{cat}$, the potential energy of each temperature replica had sufficient overlap with the neighboring replicas, resulting in an exchange rate of ~33% between each replica (Fig. S6A). Sufficient overlap of the potential energy between the individual replicas ensured that each replica could randomly "walk" through the temperature range, thereby enhancing phase space sampling. The backbone r.m.s.d. distribution of the replicas remained constant after 8 ns (320 ns total = 8 ns × 40 replicas) of simulation, indicating system convergence (Fig. S6B). The distance between His[260] and the β-hydroxy of MA

Figure 5. MD models of the mycolated Ag85C intermediate. *A*, Ag85C-MA-His[260]seq. *B*, Ag85C-MA-His[260]cat. *C*, hydrogen bonding of His[260] with Ser[148] in the sequestered position was stable during MD simulations. When His[260] was placed in the catalytic position without an acceptor molecule present the side chain freely samples conformations, making limited hydrogen-bonding interactions with the β-hydroxy of MA.

Figure 6. MD model of the mycolated Ag85C intermediate with acceptor molecule present. *A*, Ag85C-MA-trehalose MD model. *B*, in the catalytic position when an acceptor molecule is present, His[260] exclusively sampled both the 6′-hydroxy of trehalose and the β-hydroxy of MA.

and the distance between the nucleophilic Ser[124] and the α9-helix are plotted as a 2D heat map (Fig. 8). When both of these distances are small, the enzyme is in the catalytic state. Alternatively, when the distance between His[260] and β-hydroxy of MA was large (>5 Å), two states were observed. In state 1, the α9-helix was kinked toward the active site, similar to what was observed in the catalytic state, but the distance between His[260] and β-hydroxy of MA was between 5 and 7 Å. In the T-REMD simulations, the enzyme transitioned toward the relaxed form of the enzyme (state 2). In state 2, the α9-helix was farther away from the active site, whereas His[260] remained dynamic and sampled many conformations. Importantly, in many of these states, His[260] moved closer to Ser[148] but never formed a hydrogen bond with the hydroxy of Ser[148]. The conformations of His[260] observed in the initial conventional MD simulation of Ag85C-MA-His[260]cat are consistent with the corresponding REMD simulations, suggesting that the shorter simulations were sufficient to obtain meaningful conformational sampling of the active site.

Discussion

THL, known commercially as Orlistat, is a synthetically stable derivative of lipstatin, a natural product synthesized by *Streptomyces toxytricini* that inhibits the human pancreatic lipase (19, 20). THL was shown to inhibit the thioesterase domain of the human fatty-acid synthase (FAS) (21). Functioning as a versatile lipid esterase inhibitor, THL exhibits growth

inhibition on *M. tuberculosis* via covalent modification of various endogenous lipid esterases; Ag85C is reported as one of 14 validated targets (13). Here, we have shown that covalent inhibition occurs within minutes, and initial binding affinities are in the low μM range (8.7 ± 0.7 μM), resulting in a k_{inact}/K_I of 7.9 ± 1.0×10^{-3} μM^{-1} min^{-1}. This value falls within the range of previously reported values for ebselen-derived covalent inhibitors of Ag85C that are known to efficiently inhibit *M. tuberculosis* growth (15).

A significant difference in THL inhibition of Ag85C compared with human FAS is the lack of observed hydrolysis of the covalent enzyme adduct. The structure of FAS in complex with THL contains two molecules in the asymmetric unit: one with an intact ester linkage and the other in a hydrolyzed form (22). A later study found that movement of the hexanoyl tail resulted in the repositioning of the β-hydroxy of THL (23). Repositioning of the β-hydroxy disrupts hydrogen bonding to the stationary catalytic histidine, allowing for water activation and subsequent hydrolysis of the acyl-enzyme intermediate (23). However, in the Ag85C-THL structure, we found that covalent modification results in structural changes, specifically the catalytic histidine, His[260], is physically displaced by the peptidyl side arm and is instead within hydrogen-bonding distance to neighboring Ser[148] (Fig. 4A). The sequestered positioning of His[260] to Ser[148] was shown to be stable via MD simulations, thereby limiting water activation and subsequent hydrolysis of
Figure 7. Nucleophilic activation pathways for the second half-reaction (*6*OH* denotes the mycolated hydroxy of TMM). *A*, direct activation of the 6′-hydroxy of TMM for the second half-reaction by His[260], stabilized by the β-hydroxy of MA. *B*, indirect activation scheme proceeding through a proton transfer from the β-hydroxy of MA to His[260] followed by the proton transfer from the 6′-hydroxy to deprotonated β-hydroxy of MA.

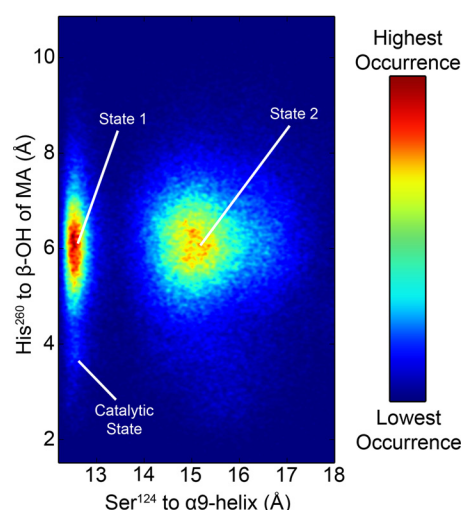

Figure 8. Heat map of Ag85C-MA-His[260]cat conformations sampled during the REMD simulation. The starting catalytic position was not frequently sampled when the α9-helix remained kinked toward the active site in the catalytic position; instead His[260] randomly sampled phase space, similar to what was observed in the initial MD simulation (state 1). In state 2, the α9-helix relaxes, similar to what is observed in the sequestered form. Although His[260] is positioned toward Ser[148], a stable hydrogen bond to Ser[148] is never observed.

Ag85C-THL. This stable interaction is experimentally supported as Ag85C was successfully crystallized with THL in only a slight molar excess of THL to enzyme, 1.2:1, respectively.

A similar displacement of His[260] toward Ser[148] is observed in both the tetrahedral intermediate (represented by the Ag85C-diethyl phosphate complex) and the nucleophilic S124A mutant structures (Fig. 4*A*) (7, 12). Although both of these structures lack a bulky substituent to force the dislocation of His[260], the side chain of His[260] occupies the sequestered conformation due to structural rearrangement resulting from hydrogen bond disruption between His[260] and the nucleophilic serine (12). Therefore, we hypothesized that the acyl-enzyme intermediate form of Ag85C increases the number of conformations that are energetically accessible for His[260], which results in limiting the hydrolysis of the acyl-enzyme intermediate. The sequestered conformation is one of the many conformations that His[260] can adopt in the acyl-enzyme intermediate that may prevent water binding at the site necessary for nucleophilic attack on the acyl-enzyme intermediate. Indeed, many conformations of His[260] were observed in the MD simulation of the Ag85C-MA-His[260]cat model. In general, His[260] was observed to be >5 Å from the β-hydroxy of MA, positioning the imidazole ring away from the acyl-enzyme ester moiety, prohibiting His[260] to act as a general base. However, His[260] did sample conformations near the acyl-enzyme ester, allowing for potential water activation. This observation would therefore be consistent with the low levels of hydrolysis observed in solution (Fig. S4). To enhance the sampling of thermodynamically accessible conformations, we conducted T-REMD simulations of the acyl-enzyme intermediate. In addition, during the T-REMD simulations, the system transitioned toward the sequestered form, but a hydrogen bond did not form between His[260] and Ser[148]. In the mutant activity studies, low levels of hydrolytic activity persisted when the highly conserved Ser[148] was mutated to alanine or threonine to investigate a potential role for Ser[148] in sequestering His[260]. Similar to the wildtype enzyme, we attributed this residual hydrolytic activity to His[260] sampling active conformations. Interestingly, the Ser[148] mutants did lose all detectable acyltransferase activity, indicating that Ser[148] plays a role in the molecular positioning of the acceptor molecule with the active site of Ag85C.

In the relaxed structural form, the α9-helix and the connecting loop to the β7-strand accompany the displacement of His[260], which has been observed in numerous Ag85C structures with either allosteric covalent modification or perturbation of the catalytic triad (7, 12, 14, 15). In each case, the dynamic loop falls into the active site due to α9-helix relaxation (Fig. 4, *A* and *B*). Restructuring of the dynamic loop results in the side chain of Leu[217] being positioned in the same location as the peptidyl side arm of THL in the Ag85C-THL structure, further hindering water activation by His[260] (Fig. 4*B*). Unfortunately, the loop configuration associated with the fully sequestered form of the enzyme, which is observed crystallographically, was not sampled in any of the performed MD or REMD simulations. Whether the enzyme fully adapts the hypothesized sequestered form or not, there is sufficient structural, computational, and enzymatic evidence to suggest that *M. tuberculosis* Ag85s evolved to limit hydrolysis of the acyl-enzyme intermediate
Figure 9. Proposed structure-based catalytic cycle of Ag85s. The *light blue surface* corresponds to the α9-helix and dynamic loop, *yellow* corresponds to the MA-binding site, and *red* corresponds to the sugar-binding site. *A*, apoenzyme exhibits a large TMM$_1$-binding site (Protein Data Bank code 1DQZ) (7). *B*, Ag85C octyl thioglucoside structure mimics the initial TMM$_1$ binding event (Protein Data Bank code 1VA5) (8). *C*, tetrahedral transition state (*TS*) of the first half-reaction (*RXN*) represented by the Ag85C-diethyl phosphate structure with His^{260} sequestered and the α9-helix relaxed (Protein Data Bank code 1DQY) (7). A free trehalose molecule leaves, completing the first half-reaction. *D*, model of the Ag85C-MA intermediate based on the Ag85C-THL structure. *E*, the second half-reaction proceeds through the binding of TMM$_2$ or AG to the sugar-binding site. The α9-helix and His^{260} are restored to the catalytic position as a result of acceptor binding. The model of Ag85C-MA-trehalose is shown. *F*, transition state for the second half-reaction, again modeled by Ag85C-diethyl phosphate, leading to the formation of TDM or mAG and subsequent product release (Protein Data Bank code 1DQY) (7).

through structural rearrangements stimulated by enzyme acylation.

The previous understanding of the mycolated form of Ag85s was that the α-chain of MA was buried in the hydrophobic hole while the meromycolate chain was flipped outward into the mycomembrane (9). However, the positioning of the resulting bound mycolic acid in relation to the secondary trehalose-binding site is problematic for catalysis of TDM for two reasons. First, this mycolated form would be too sterically hindered to allow an incoming acceptor molecule from the secondary site to enter the active site (9). Second, this positioning would preclude nucleophilic attack by TMM on the carbonyl intermediate because geometric requirements for nucleophilic attack could not be met (24). The incorrect alignment of the carbonyl relative to the oxyanion hole would not allow for stabilization of the oxyanion intermediate (7). Additionally, this scheme does not account for mAG synthesis. Together, these factors further negate the interfacial mechanism model and the proposed coordination of substrate as a function of enzymatic reaction progression. Therefore, an alternative arrangement of MA and the incoming acceptor molecule within the Ag85 active site is required.

We propose that both the α-alkyl chain of the MA and the portion of the meromycolate chain proximal to the ester linkage most likely lie within the active site hydrophobic cleft. The region of the meromycolate chain distal to the ester linkage may remain embedded in the mycomembrane. This positioning properly orients the carbonyl of the acyl-enzyme intermediate toward the oxyanion hole. Furthermore, it allows for nucleophilic attack from the respective 6′- or 5-hydroxy of either trehalose of TMM or arabinose of the AG upon binding to the identified sugar-binding site of the active site. Two potential pathways for the activation of the incoming nucleophile are

therefore chemically viable based on this binding mode and were exclusively sampled in the Ag85C-MA-trehalose MD simulation (Figs. 6 and 7). Central to both pathways is the β-hydroxy of MA as it is positioned to allow for either direct or indirect activation of the incoming nucleophile based on the stable catalytic conformation of His^{260} in the presence of trehalose (Fig. 7).

Indirect activation would proceed through a concerted proton transfer from the β-hydroxy of MA to His^{260} while the proton is being transferred from the incoming nucleophilic hydroxy of the acceptor molecule to the β-hydroxy of MA (Fig. 7B). The now deprotonated hydroxy is free to undergo nucleophilic attack on the acyl-enzyme ester. The indirect pathway is chemically feasible and would be similar to a proton shuttle mechanism (25–27). The more conventional, direct activation pathway would consist of a simple proton transfer from the incoming hydroxy nucleophile by His^{260} (Fig. 7A). Again, the deprotonated hydroxyl is now free to undergo nucleophilic attack on the acyl-enzyme ester. Regardless of the pathway chosen, the β-hydroxy of MA stabilizes the deprotonated nucleophile prior to nucleophilic attack. Therefore, the final reduction of the β-ketone of MA to β-hydroxy during biosynthesis of MA is required for Ag85 catalysis (4).

Our proposed organization of substrates and intermediates as the reaction proceeds is depicted in Fig. 9 and outlined in the corresponding figure legend. The proposed alternative model satisfies the issues raised with the previous model and highlights the importance of the dynamic nature of the α9-helix in the enzymatic activities of Ag85A, -B, and -C (11). Specifically, this arrangement of substrates in the enzyme explains how both TMM and AG can act as acceptor molecules and why both are selectively mycolated on the 6′- or 5-hydroxy, respectively. Therefore, the secondary trehalose-binding site is not neces-

sary for this catalytic reaction scheme, but the affinity for trehalose and sugar-based detergents cannot be ignored (8, 9). As a consequence of the conformational change between native and acyl-enzyme forms, the secondary binding site changes shape and thereby likely changes the affinity of this site for carbohydrates. Therefore, it seems most likely that the secondary binding site of Ag85 has affinity to trehalose to maintain Ag85 at the surface of the mycomembrane. This association is most important in the native form of the enzyme where it interacts with the mycomembrane surface through non-covalent interactions but is less important when Ag85 is in a covalent complex with an MA that is embedded in the mycomembrane.

The Ag85C-THL structure and findings presented in this study should facilitate the design of new THL-derived drugs with higher specificity for *M. tuberculosis* Ag85s while avoiding other, non-essential *M. tuberculosis* and human lipid esterases. Conversely, the findings of this study can influence modifications to THL that potentially enhance inhibition of other lipid esterases outside of *M. tuberculosis*. In particular, this structure highlights the important role of the peptidyl side arm in extending the lifetime of the covalent enzyme-inhibitor complex and should inform the design of covalent α/β-hydrolase inhibitors to prevent activation of water. With regard to *M. tuberculosis* and general acyltransferase chemistry, the mycolated enzyme intermediate model affords visualization of every step of the catalytic cycle and a better understanding of mycolyltransferase catalysis while rationalizing the chemical need for the β-hydroxy of MA. Ultimately, these catalytic insights can be applied to the entire α/β-hydrolase superfamily, providing a better understanding of how these enzymes conduct unique catalytic functions despite a common fold and catalytic triad.

Experimental procedures

WT and mutant molecular cloning

The *M. tuberculosis* *fbpC* gene was previously cloned into a pET-29a plasmid as described (14). The recombinant Ag85C expression construct included a non-cleavable C-terminal polyhistidine tag. S148A and S148T mutants were generated using the Agilent QuikChange® Lightning kit. The plasmid harboring the WT *fbpC* gene was used as the template for both mutagenesis reactions with primers 5′-ggttgaggaagcccgccaac-gacgcggcgta-3′, 5′-ggttgaggaagcccgtcaacgacgcggcgta-3′, and corresponding complements used for the S148A and S148T mutants, respectively.

Protein expression and purification

Recombinant *M. tuberculosis* WT Ag85C was expressed and purified as previously published with S148A and S148T following identical experimental procedures (14). In short, chemically competent T7 Express *Escherichia coli* cells were transformed with the desired pET-29a C-terminal polyhistidine construct. Inoculated cultures were grown at 37 °C in Luria-Bertani broth to a density of 0.6 $A_{600\ nm}$. Incubation temperature of the cultures were then dropped to 16 °C, and protein expression was induced with 1 mM isopropyl β-D-1-thiogalactopyranoside. After 24–36 h, induced cultures were harvested and resuspended in 20 mM Tris pH 8.0 buffer containing 5 mM β-mercaptoethanol and placed at −80 °C for storage.

Induced cells were thawed, lysozyme and DNase I were added and incubated on ice, and cell lysis was complete following sonication. The crude cellular lysate was clarified by centrifugation and loaded onto a metal (cobalt) affinity chromatography column equilibrated with lysis buffer. Following washing with lysis buffer, protein was eluted with a gradient of imidazole (0–150 mM). Eluted protein was pooled and loaded onto a 5-ml anion exchange column equilibrated with washing buffer (20 mM Tris pH 8.0 buffer containing 1 mM EDTA and 0.3 mM tris(2-carboxyethyl)phosphine). Following washing, protein was eluted with a 0–1 M NaCl gradient. Eluted protein was pooled and subjected to ammonium sulfate precipitation (2.8 M). Precipitated protein was pelleted via centrifugation and resuspended in 10 mM Tris, pH 7.5, 2 mM EDTA for crystallization or 50 mM sodium phosphate, pH 7.5, for enzymatic assays. Resuspended protein was dialyzed overnight against the respective buffer to remove residual ammonium sulfate.

Crystallization and data collection

Recombinant Ag85C was concentrated to 150 μM ($\sim$5 mg/ml). Ag85C-THL crystals were obtained through cocrystallization via incubation of THL (20 mM stock in DMSO) at a 1:1.2 molar ratio of protein to compound for 90 min on ice prior to drop setup. Using the hanging drop method, crystals formed after a week at 16 °C in a 1:1 protein to well solution (0.1 M calcium chloride dehydrate, 0.05 M Bis-Tris, pH 6.5, 22.5% (v/v) ($\pm$)-2-methyl-2,4-pentanediol, Hampton Research Index HR2-144). Crystals were cryoprotected through the addition of 0.2 μl of glycerol (10% (v/v) final drop concentration) immediately prior to looping and flash cooling in liquid nitrogen. X-ray diffraction data were collected at 100 K using synchrotron radiation (λ = 0.97872 Å) on beam line F of Life Sciences Collaborative Access Team, Advanced Photon Source at Argonne National Laboratory.

Structure determination and refinement

Diffraction data were indexed, integrated, and scaled using HKL2000 (28). The resulting diffraction data set was indexed and scaled as $P2_12_12$. The phase solution came from molecular replacement using the native Ag85C structure (Protein Data Bank code 1DQZ) with one molecule determined to be in the asymmetric unit. Residues not fitting $2F_o − F_c$ electron density were deleted, and the resulting model was subjected to a rigid body refinement followed by simulated annealing (phenix.refine) (29). Deleted residues and the THL-modified Ser[124] were built manually using Coot (30). Restraints for the THL-modified Ser[124] were generated with eLBOW (31). Glycerol and ($\pm$)-2-methyl-2,4-pentanediol molecules were added using Ligand Fit (32). The progressing model was subjected to rounds of XYZ coordinate, real-space, occupancy, and B-factor refinements in between manual builds and ligand additions (phenix.refine) (29). Model building and refinement ended when R_{work} and R_{free} values of 0.163 and 0.167, respectively, were reached with 97% of residues being Ramachandran favored and 1% being outliers. Model statistics were validated with MolProbity (33). The two outlier residues, Gly[29] and Ser[86], have been flagged as outliers in prior Ag85C structures (12). These residues are found within loop regions and are positioned based on the dif-

SASBMB

J. Biol. Chem. (2018) 293(10) 3651–3662 **3659**

ference density maps giving correlation coefficients of 0.97 and 0.86 for those two residues, respectively.

Enzymatic and inhibition assays

A previously described fluorescence-based assay was used to monitor transesterase activity (14). For inhibition studies, THL was serially diluted from a 30 mM stock in DMSO, resulting in a range of final reaction concentrations of $300-12.5$ μM. Kinetic reads were initiated following the titration of resorufin butyrate immediately after the titration of THL or an equal volume of DMSO. Kinetic reads were conducted at 37 °C in a 50 mM sodium phosphate buffer, pH 7.5, using $\lambda_{ex} = 500$ nm and $\lambda_{emit} = 590$ nm. Relative fluorescent units were converted to product concentration using a previously established standard curve methodology (15). Background water hydrolysis of resorufin butyrate was subtracted from the triplicate data, and the rates were determined using Prism 7 with a one-phase association equation: $Y = Y_0 + (\text{Plateau} - Y_0)(1 - \exp(-kx))$ where $x =$ time, $Y = [\text{Product}]$, $(Y_0 + (\text{Plateau} - Y_0)) = V_i/k_{obs}$, and $k = k_{obs}$. k_{inact}/K_I was determined by plotting the k_{obs} *versus* inhibitor concentration and fitting the data with the equation $k_{obs} = k_{inact}/(1 + (K_I/[I]))$ (34).

Enzymatic activity for mutants was determined with an identical assay as described above. Conditions for transesterase activity were as follows: 500 nM respective enzyme, 4 mM trehalose (500 mM buffer stock), and 100 μM resorufin butyrate (10 mM DMSO stock). Kinetic reads were initiated immediately following the titration of resorufin butyrate. For hydrolase activity, reactions were identical sans trehalose. Data were converted to product concentration, background water hydrolysis of resorufin butyrate was subtracted from all triplicate data, and rates were determined using Prism 7 with a linear fit. Reported transesterase activity has the enzymatic rate of resorufin butyrate hydrolysis subtracted.

Sequence alignments

The sequences of 464 known mycolyltransferases were aligned using Clustal Omega (35). The resulting alignment was used to generate the probability of a given amino acid at a determined position, indicating sequence conservation. Figures were generated using WebLogo 3 (36).

Molecular modeling and MD simulations

The X-ray crystal structure presented (Protein Data Bank code 5VNS) was used as the model for the Ag85C-THL simulations. For the Ag85C-MA sequestered/catalytic and Ag85C-MA-trehalose classical MD simulations, the models generated were adapted from the Ag85C-THL and Ag85-trehalose X-ray structures. Because of the structural similarities of THL and MA, the Ag85C-THL crystal structure permitted a straightforward transformation to the mycolated acyl-enzyme intermediate form of the enzyme. For the starting Ag85C-MA model, we kept the alkyl chain lengths the same as those observed in the THL structure while inverting the observed stereochemistry of THL to that of MA; additionally, the peptidyl side arm of THL was removed. THL was modified to mimic MA and then used to generate the ligand using eLBOW (31). The resulting MA molecule was manually positioned in the active site with PyMOL

(37), and the final coordinates were then inserted into the Ag85C model in place of THL. The MA alkyl chain atoms were modeled based on the $2F_o - F_c$ density for THL. The final MA model was subjected to bond angle refinement in Coot (30). Upon alignment of the Ag85C-THL structure or the resulting Ag85C-MA model with the previously published Ag85B-trehalose structure (Protein Data Bank code 1F0P), it became apparent that the 6′-hydroxy is positioned for nucleophilic attack on the carbonyl intermediate (9). We therefore modeled trehalose as an incoming acceptor molecule. In the crystal structure of Ag85C-THL, His[260] is displaced away from the catalytic position by the peptidyl moiety of THL. Thus, His[260] was shifted back to the catalytic position by aligning Ag85C-THL to the Ag85B-trehalose structure. The dynamic loop in each model was rebuilt using the program Coot (30). The protonation states of Ag85C at pH 7.5 were assigned using PROPKA with the PDB2PQR sever (38). The net charge of Ag85C was -6. Each substrate used in the MD simulations had an overall neutral charge.

Molecular mechanics force field parameters were generated for MA, THL, and trehalose as follows. Each substrate model was subjected to geometry optimization with Gaussian 09 (39) at the HF/$6-31$G* level of theory. Specifically, for the covalently linked substrates (THL-Ser[124] and MA-Ser[124]) the serine backbone was capped with a (-CO-CH$_3$) C-terminal cap and an (-NH-CH$_3$) N-terminal cap. Following geometry optimization, the electrostatic potential of each substrate was computed at the same level of theory. Atomic partial charges were calculated by restrained electrostatic potential charge fitting using the program R.E.D. (40). The antechamber module of AMBER16 was then used to assign atom types from the general AMBER force field for both THL and MA, and the GLYCAM_06j-1 force field was used for trehalose (41–43).

Each model was generated with the leap module of AMBER16 using the ff14SB force field to describe the protein (43). Crystallographic water molecules were retained, and each system was further solvated in a cubic box of TIP3P water with at least 20 Å between the protein and the nearest face of the solvent box (44). Six Na$^+$ counterions were added to neutralize the charge of the system. The system was then subjected to 1000 steps of steepest descent minimization followed by 250 steps of conjugate gradient minimization. For the MD simulations, periodic boundary conditions were applied, and the particle mesh Ewald method was used to evaluate long-range electrostatic interactions (45). A cutoff of 8 Å was used for real-space nonbonded interactions. The SHAKE algorithm was used to constrain all bonds to hydrogen, allowing the use of a 2-fs time step (46). Prior to production MD simulation, the system was equilibrated in three steps. First, the system was heated from 0 to 300 K over 500 ps with Langevin dynamics and a collision frequency of 1 ps^{-1}. During the first equilibration step, all heavy atoms of the protein and ligand(s) were subjected to a harmonic restraint potential of 5 kcal mol^{-1} Å^{-2}. The second equilibration step consisted of a 500-ps simulation at constant pressure (1 atm) with isotropic scaling, again with heavy atoms harmonically restrained. In the third 500-ps equilibration step, only the Cα atoms were restrained. Each system was then subjected to 100-ns unrestrained production MD.

For the T-REMD simulations, the systems were equilibrated using the same approach as for the standard MD equilibration except that the final temperature of each replica was selected based on the temperature distribution, which was calculated as follows. Four systems were equilibrated at 280, 306, 332, and 358 K. The average energy was then computed from these four systems. The average energy as a function of temperature was fitted to a polynomial, allowing iterative solution of the Monte Carlo criterion with an exchange rate of 0.3 (18). The resulting temperature distribution was 299.2, 300.4, 301.6, 302.8, 304.1, 305.3, 306.5, 307.7, 308.9, 310.2, 311.4, 312.7, 313.9, 315.2, 316.4, 317.7, 319.0, 320.3, 321.5, 322.8, 324.1, 325.4, 326.7, 328.0, 329.3, 330.6, 331.9, 333.2, 334.5, 335.9, 337.2, 338.5, 339.9, 341.2, 342.6, 343.9, 345.3, 346.6, 348.0, and 349.4 K. The production T-REMD simulations were performed in the NVT ensemble. The time between exchanges was 0.5 ps, and each system was evolved for 12 ns, yielding a total of 12 ns $\times$ 40 replicas = 480-ns cumulative simulation time. During the simulation, the frames were recorded every ps, and all frames were used during the data analysis, which was performed with the pytraj module (47, 48).
