# Abstract

The double Maddox rod test is often use to measure cyclodeviations and to monitor change over time. The purpose of this study was to estimate test–retest reliability and the amount of cyclodeviation that would be considered real change using 95% limits of agreement. We retrospectively studied 86 clinically stable patients with double Maddox rod measurements 5–175 days apart (median, 69 days). The range of cyclodeviation at the first measurement was 6° incyclodeviation to 15° excyclodeviation. We calculated the half width of the 95% limits of agreement to be 4.7°, which means that a change of  $5^{\circ}$  in cyclodeviation would be considered a real change. The threshold of  $5^{\circ}$  should be used when assessing change between two measurements made with double Maddox rods.

Determining the degree and direction of a cyclodeviation is important for the diagnosis and management of certain types of strabismus. Currently, one of the most frequently used methods of measuring cyclodeviations subjectively in clinic is the double Maddox rod test. This test has often been used as an outcome measure in previous studies, for example, when comparing the effectiveness of different torsional surgical procedures in patients with superior oblique palsy<sup>1</sup> or to assess torsional side effects.<sup>2</sup> Nevertheless, test–retest data for the double Maddox rod test are not available in the literature. The present study aimed to quantify test–retest variability in two consecutive double Maddox rod measurements.

# **Subjects and Methods**

This study was approved by the Mayo Clinic Institutional Review Board. All procedures and data collection were conducted in a manner compliant with the US Health Insurance Portability and Accountability Act of 1996 and all research procedures adhered to the tenets of the Declaration of Helsinki.

The medical records of patients seen at the Mayo Clinic from September 2004 to October 2016 were reviewed retrospectively to identify a cohort of stable strabismus patients, with

measures of ocular alignment by distance and near prism and alternate cover test on two examinations at least 1 day but no more than 180 days apart and measures of torsion by double Maddox rod. Stable ocular alignment was defined as distance and near measures within 5 on each examination (and no change in direction of the vertical deviation). This 5 limit is well within previous reports of test–retest variability for prism and alternate cover test strabismus measurements.<sup>3</sup> Patients with any level of visual acuity were included, but patients were excluded if both streaks of the double Maddox rod test could not be seen simultaneously. Patients whose history included any of the following during the previous 5 years were excluded: head trauma, neurosurgery, unstable neurologic conditions (chronic progressive external ophthalmoplegia, myasthenia, multiple sclerosis, superior oblique myokymia), or eye surgery possibly affecting cyclodeviation (strabismus, orbital decompression, cataract, trabeculectomy/glaucoma drainage device, orbital fracture repair, vitreoretinal surgery, ptosis or lid surgery, botulinum toxin). Patients diagnosed with trochleitis and oscillopsia were also excluded.. Nonsurgical treatments (eg, prism) were allowed, with the exception of prolonged full-time occlusion.<sup>4</sup>

#### Assessment of Torsion

Cyclodeviation was assessed using the double Maddox rod test at both examinations by the same examiner. The examiner routinely performed the test as essentially masked, not reviewing the results of previous examinations until all testing was completed. The patient was tested in a sitting position, wearing a full trial frame (eFigure 1), with the red lens placed in front of the right eye and the white lens placed in front of the left eye. A muscle light was then presented in the straight ahead position, and the patient was asked whether or not they saw two horizontal streaks. The lenses were then deliberately offset by the examiner, with the red lens at approximately  $105^{\circ}$  and the white at approximately  $75^{\circ}$ , and the patient was instructed to adjust the knobs of the trial frame slowly (right lens and then left lens) until the perceived two horizontal streaks were "parallel to the floor" and "running like train tracks" or "together as one line." The torsional deviation was read on the trial frame to the nearest single degree (estimating number of degrees between the  $5^{\circ}$  markings on trial frame), and the sum from both eyes was recorded as the net cyclodeviation. For example,  $5^{\circ}$  incyclodeviation on the right and  $7^{\circ}$  excyclodeviation on the left would be read as  $2^{\circ}$  excyclodeviation.

#### Analysis

Differences between test and retest were calculated for each individual. The 95% limits of agreement and the 95% confidence intervals around the 95% limits of agreement were calculated. Test–retest data were also presented as a Bland-Altman plot.<sup>5</sup>

## Results

A total of 86 patients (mean age, 52 years; range, 14–86 years) met inclusion criteria. Demographics and clinical characteristics are presented in Table 1.

First measurement of cyclodeviation ranged from  $6^{\circ}$  incyclodeviation to  $15^{\circ}$  excyclodeviation. The second measurement ranged from  $10^{\circ}$  incyclodeviation to  $17^{\circ}$ 

excyclodeviation. The range of difference was 5° incyclodeviation to 7° excyclodeviation, with a mean of  $0.5^{\circ}$  excyclodeviation. Bland-Altman plots are presented in Figure 1, showing no evidence of increasing variability with increasing magnitude. The half-width of the 95% limits of agreement was 4.7° (95% CI, 3.8°–5.5°), with 95% limits of agreement of 4.2° incyclodeviation to 5.2° excyclodeviation.

### Discussion

In the present test–retest variability study of cyclodeviation using the double Maddox rod test, the half-width of the 95% limits of agreement was 4.7°. Therefore, to be confident that a real change in cyclodeviation has occurred, a change of 5° between examinations would be needed, acknowledging that any difference in measurements has both a component of measurement error and possible real change.

We are unaware of previous studies calculating test–retest variability for subjective cyclodeviation using the double Maddox rod test in patients. In a recent study of the single Maddox rod test (using the average of 3 measurements on each examination) in 20 subjects,<sup>6</sup> the 95% limits of agreement (calculated from the author's published averages from each patient) was 4.7°, which is essentially the same as that of the present study using the double Maddox rod.

Some limitations to the double Maddox rod test for measuring cyclodeviation have been previously reported.<sup>7</sup> The Maddox rods are somewhat challenging to measure to the single degree, because the trial frames are graduated in 5° increments. In addition, we did not study test–retest variability within a single examination; nevertheless, we believe our study of test–retest variability between examinations is clinically useful.
