ABSTRACT

Objective: Chronic thromboembolic disease (CTED) is characterized by persistent pulmonary thromboembolic occlusions without pulmonary hypertension. Early surgical treatment by performing pulmonary endarterectomy (PEA) may improve symptoms. The goal of the study was to review our experience and early outcome of PEA in patients with CTED.

Methods: Data were prospectively collected on all patients who underwent PEA between 2011 and 2015. Patients with CTED and a mean pulmonary artery pressure (mPAP) of <25 mm Hg were identified. All patients were in New York Heart Association (NYHA) functional class II or III. Measured outcomes were in-hospital complications, improvement in cardiac function and exercise capacity, and survival after PEA. Patients were reassessed at 6 months following surgery.

Results: A total of 23 patients underwent surgery. There was no in-hospital mortality, but complications occurred in six patients (26%). At 6 months following surgery, 93% of the patients remained alive. Following PEA, the mPAP fell significantly from 21.0±2.7 mm Hg to 18.2±5.5 mm Hg (p<.001). Pulmonary vascular resistance also significantly decreased from 2.2±0.7 wood to 1.5±0.5 wood (p<.001). The 6-min walking distance significantly increased from 322.6±80.4 m to 379.9±68.2 m (p<.001). There was a significant symptomatic improvement in all survivors in NYHA functional classes I or II at 6 months following surgery (p=.001).

Conclusion: PEA in selected patients with CTED resulted in significant improvement in symptoms. The selection of patients for undergoing PEA in the absence of pulmonary hypertension must be made based on patients' expectations and their acceptance of the perioperative risk. Introduction

Chronic thromboembolic pulmonary hypertension (CTEPH) is a serious long-term complication of pulmonary thromboembolism (PTE) and results from incomplete resolution of vascular obstruction (1, 2). This may be associated with triggered vascular remodeling, which causes persistent elevation in pulmonary artery pressure (PAP) and pulmonary vascular resistance (PVR), leading to right ventricular failure (3-5). CTEPH is a progressive disease associated with considerable morbidity and mortality. It has an estimated incidence of 0.5 to 3.8% following acute PTE (4, 6). Mortality is usually associated with progressive pulmonary hypertension and resulting right ventricular (RV) failure (4, 5). Pulmonary endarterectomy (PEA) is the most effective therapy

in CTEPH, and in centers with the most experienced surgeons, the overall mortality rate due to PEA is less than 5% (5, 7-9). PEA removes obstructive thromboembolic material and significantly improves the hemodynamic measures of PVR, PAP, and cardiac output. PEA also causes reverse remodeling of the right ventricle, with the return of RV systolic and diastolic function toward normal levels (7, 8). Long-term survival rates have been reported to reach 90% at 5 years following surgery (10). Recently, a growing number of patients have been identified as having persistent dyspnea after PTE in the absence of pulmonary hypertension (mean PAP <25 mm Hg) (11). The term chronic thromboembolic disease (CTED) has been used for these patients, and the cause of persistent symptoms have been suggested to be associated with dead space ventilation, pulmonary hypertension with ex-

ercise, and/or maladaptation of the right ventricle to decreased RV compliance (11-16). At present, neither the prognosis nor the risk of progression to more a severe form of pulmonary hypertension in these patients is clear (17). The optimal therapeutic option has also not been defined for patients with CTED; however, an increasing number of patients have undergone PEA in expert centers over the last few years for symptomatic improvement. Recently, the Cambridge group reported their results of PEA in patients with symptomatic CTED (11). The authors reported significant improvement in symptoms and quality of life after PEA, with 95% survival rate at 1 year following surgery (11). No other study has been reported that assesses the outcome of patients with CTED following PEA. Ever since we started our PEA program with acceptable results (18), more than 450 operations have been performed, with increased institutional and surgical experience resulting in our center becoming the only expert PEA center in Turkey. This study aimed to evaluate the efficacy of PEA in the treatment of patients with CTED and presents a summary of our experience and preliminary results over a 6-month period.

Methods

Between March 2011 and December 2015, 23 patients with the diagnosis of CTED underwent PEA (Table 1). The mean age of 12 female and 11 male patients was 46.2 ± 15.2 years and ranged from 21 years to 73 years. Overall, symptom onset ranged from a period of 3 months to 120 months preoperatively, with an average period of 25.8 ± 25.2 months, and all patients were in New York Heart Association (NYHA) functional class II (n=11) or III (n=12).

Twenty patients (87.0%) presented with a history of pulmonary embolism, with one-third of patients having more than one episode and three patients (13.0%) having a history of deep venous thrombosis. Twelve patients (52.1%) had at least one comorbidity or risk factor that may be associated with PTE. Seven patients (31.8%) had some coagulation disorders associated with immunological disorders, including three patients with inherited deficiencies of protein C, protein S, or Factor V Leiden mutation; two with both antiphospholipid antibody syndrome and systemic lupus erythematosus; and two with Behçet's disease. One patient (4.5%) had a diagnosis of sarcoidosis, one (4.5%) had a history of lung cancer, one (4.5%) had sarcoma of the lower extremity, and one (4.5%) had hypothyroidism. One patient (4.5%) had steel bars behind the sternum due to a previous minimally invasive pectus excavatum operation performed 2 years ago (19). All patients had symptoms of cardiopulmonary disease despite adequate anticoagulation for at least 3 months.

CTED was diagnosed by the presence of mismatched perfusion defects on the radioisotopic ventilation perfusion (V/Q) scan despite adequate anticoagulation for at least 3 months. Evidence of CTED was then confirmed by computed tomography pulmonary angiogram (CTPA) using maximal intensity projections and right heart catheterization (RHC) with measurements of the right atrial, pulmonary artery, and pulmonary wedge pressures. diac output was determined by thermodilution, and PVR was calculated. No patient underwent either pulmonary angiography or the cardiopulmonary exercise test. Chronic thromboembolic pulmonary disease was defined as a mean PAP (mPAP) of less than 25 mm Hg on performing RHC. Our indications for PEA for patients with CTED were as follows: mPAP less than 25 mm Hg, NYHA functional class equal or greater than II, absence of significant comorbidities, and presence of surgically accessible disease.

During preoperative evaluation, all patients had completed their assessment with the 6-min walking test, pulmonary function test, duplex scanning of the lower extremities, and arterial blood gas test. Surgical candidates older than 45 years had undergone coronary angiography as part of their assessment. For patients with CTED, options of undergoing surgery for symptomatic benefits or the alternative of conservative treatment with regular follow-ups were discussed. The only surgical contraindication was underlying severe parenchymal lung disease in our center. In contrast to the Cambridge PEA group (11), we have not routinely used an inferior vena cava (IVC) filter perioperatively in our program due to the lack of evidence supporting the use of IVC filters in CTED and their potential side effects in the long-

Figure 1. Samples of pulmonary endarterectomy specimens taken from the patients included in the study

term (20). All data were prospectively collected and entered into a database, and the study was retrospectively conducted. Informed consent was obtained from the patients.

Pulmonary endarterectomy

Our surgical technique has been previously described (18). In brief, surgery was performed under general anesthesia through median sternotomy and using extracorporeal circulation with periods of circulatory arrest under deep hypothermia (18°C-20°C) for the right and left pulmonary arteries. The endarterectomy specimen was circumferentially followed down to the segmental and subsegmental branches in each lobe, until complete endarterectomy of the pulmonary vascular bed was achieved (Fig. 1). Weaning from cardiopulmonary bypass (CPB) was performed with care. Patients were maintained under anesthesia and sedated postoperatively in the intensive care unit (ICU). Extensive ventilatory and circulatory monitoring, including online measurement of PAP with an oxymetric Swan-Ganz catheter (Edwards Lifesciences, Irvine, CA), cardiac output, mixed venous oxygen saturation, and arterial blood gases, were continuously performed. The patients underwent pressure-controlled mechanical ventilation with a positive end-expiratory pressure of 6 cmH₂O and tidal volume of 8 mL/kg. Inhaled nitric oxide at doses of 15-20 ppm was given for the first 4 h postoperatively and was then gradually withdrawn. Cautious fluid and vasoactive drug administration, and aggressive diuresis were provided as long as necessary for the patients to recover. Most patients were extubated on the first or second postoperative day. Anticoagulation with unfractionated heparin was resumed at a low dose within 4-6 h after the end of surgery and progressively increased to full anticoagulation within 24 h. Oral coumadin was usually started after 48-72 h, with an international normalized ratio (INR) of around 2.5 targeted. Transthoracic echocardiography was performed within days of discharge from the hospital. All patients were followed up at 3 and 6 months. They were classified functionally according to the WHO/NYHA functional class and assessed with the 6-min walk test and echocardiogram at each follow-up visit. Baseline characteristics, perioperative data,

and postoperative assessment results were obtained from the patients' files and database for this study. The date of the last PTE, time from the last PTE to PEA, and length of in-hospital and ICU stay were noted. The incidence of complications was assessed. Operative mortality was defined as death in hospital or within 30 days of surgery. Deterioration in WHO/NYHA functional class was determined by worsening by at least one class compared with the best class achieved after PEA. Repeat RHC was performed when the patients experienced deterioration in WHO/NYHA functional class or remained in functional class III after PEA.

Statistical analysis

Data are summarized as mean±standard deviation for continuous variables and as number (or percentage) for categorical variables. Follow-up was 100% complete. The overall outcome of PEA was retrospectively reviewed. Data distribution was assessed using the one-sample Kolmogorov-Smirnov test. Significance of differences regarding continuous variables measured at baseline and at 6 months after PEA was tested using paired Student's t-test for parameters displaying normal distribution and with the Wilcoxon signed-rank test for parameters displaying non-normal distribution. The significance of differences between NYHA status before and after PEA was tested with the sign test. All statistical analyses were performed using SPSS version 16 software (SPSS Inc., Chicago, IL, USA), with p-values of less than .05 considered significant. Approval for this study was granted by the Institutional Review Board of Kartal Koşuyolu Teaching and Education Hospital (no: 2016.5/6-17).

Results

Between March 2011 and December 2015, 322 patients underwent PEA. Of these, 23 (7.1%) fulfilled the criteria of having CTED. The preoperative and intra- and postoperative characteristics of the patients are presented in Tables 1 and 2, respectively. All patients had evidence of chronic thromboembolic obstruction in the CTPA despite at least 3 months of effective anticoagulation with documented treatment compliance. None of the patients were on pulmonary vasodilator therapy at the time of hemodynamic assessment.

RHC data showed mildly elevated mean PAP and PVR values that were not high enough to fulfill the criteria for the current definition of pulmonary hypertension. The mean cardiac index was also at the lower end of the normal range.

After performing PEA, there was no in-hospital mortality. The mean CPB time, aortic cross clamp time, and circulatory arrest time were 224.3±62.4, 17.1±19.4, and 22.1±9.2 min, respectively. The mean duration of postoperative mechanical ventilation was 1.2±0.4 days. The length of ICU stay was 4.6±5.8 days, and the duration of discharge from hospital was 11.6±7.5 days.

Six patients (26.0%) had complications after undergoing PEA. The most common was supraventricular arrhythmias with two patients requiring cardioversion. 8th patient in the cohort had

Table 2. Comparison of baseline and postoperative outcomes at 6 months after pulmonary endarterectomy

Characteristics	Baseline (n=23)	6 months after PEA (n=21)	P
New York Heart Association functional class			
Class I	0	10 (47.6%)	0.001
Class II	11 (47.8%)	11 (52.4%)	
Class III	12 (52.2%)	0	
Hemodynamics			
Tricuspid regurgitation velocity, m/s	2.3±0.7	2.1±0.6	0.002
6-min walking distance, m	322.6±80.4	379.9±68.2	<0.001

Data are presented as n or mean±SD. PEA - pulmonary endarterectomy; the sign test was used for testing the difference between the baseline and postoperative New York Heart Association status, and the paired sample t-test was used for testing the difference between the baseline and postoperative tricuspid regurgitation velocity and 6-min walking distance

difficulty in weaning and required tracheostomy. This patient required postoperative noninvasive ventilatory support with continuous positive airway pressure, which was mainly as treatment for hypoxia due to reperfusion injury. One patient had to return to the operating theatre (for cardiac tamponade). One patient had reversible acute renal failure requiring hemodialysis. One patient also had transient vocal cord paralysis.

Two patients (8.6%) died after they were discharged from hospital. One was a female aged 51 years who died at her local hospital 5 months after PEA due to acute myocardial infarction. The second patient was a male aged 71 years and who was discharged with tracheostomy. He suddenly died at home 63 days after surgery. A post mortem examination was not performed, and his death was listed as an unexplained sudden death.

Hemodynamic parameters

Twenty-one patients (91.4%) had their comprehensive review at 6 months after surgery. Postoperative results are displayed in Table 2. Immediately after PEA, the mPAP fell significantly from 21.0±2.7 mm Hg to 18.2±5.5 mm Hg ($p<.001$). PVR also significantly decreased from 2.2±0.7 wood to 1.5±0.5 wood ($p<.001$). The 6-min walking distance significantly increased from 322.6±80.4 m at baseline to 379.9±68.2 m at 6 months after surgery ($p<.001$). Tricuspid regurgitation jet velocity was also observed to significantly decrease, and none of the patients developed pulmonary hypertension.

Atherosclerotic changes with organized thrombus, myxoid degeneration, vascular proliferation, recanalization, and fibrosis were observed in the histological analysis of pulmonary artery sections. No plexiform lesion was observed.

There was significant symptomatic improvement; 10 patients (47.6%) were in NYHA functional class I and 11 (52.3%) were in NYHA class II at 6 months ($p<.001$ for the difference compared with baseline).

Discussion

Over the past few years, an increasing number of patients with symptomatic CTED in the absence of pulmonary hyperten-

sion have undergone PEA in expert centers to improve their symptoms and quality of life (9, 11, 16). In the present study, PEA resulted in significant improvement in symptoms and the quality of life in our patients with CTED during the sixth month after surgery. In-hospital mortality was 0%, but complications occurred in 26% of the patients. To date, CTED has been poorly characterized. Recently, de Perrot and Mayer (17) have proposed a new term, chronic thromboembolic pulmonary arterial disease, instead of CTED for patients with symptomatic disease without pulmonary hypertension. Symptomatic CTED is an increasingly identified diagnosis after PTE. There is a wide degree of variation in the resolution of thrombi after PTE, and more than 50% of patients have been reported to have persistent perfusion defects 6 months after PTE (20). Although most of these patients become symptomatic, only a minority of them (0.5-3.8%) develop pulmonary hypertension (4, 6). It has been known that >60% of the pulmonary vasculature must be occluded to develop pulmonary hypertension after PTE (11, 21, 22). Severe pulmonary hypertension out of proportion to the degree of vascular obstruction is commonly seen in patients with CTEPH, which points to the development of small vessel vasculopathy in an unobstructed vascular bed (3). The predictors of small vessel vasculopathy have not been clearly defined at present. The incidence of CTED appears to be low in our cohort of patients, representing 7.1% of the patients who had undergone PEA.

Held et al. (15) analyzed the exercise capacity and limiting factors in 10 patients with CTED and compared RHC and cardiopulmonary exercise test results of patients with CTEPH and control patients. They found that patients with CTED show reduced oxygen uptake and work rate. They concluded that patients with CTED show objective functional impairment and similar limitations to patients with CTEPH. Functional limitation is characterized by gas exchange disturbance and ineffective ventilation. Our patients, as reported here, when compared to CTEPH registry patients (23), are younger (46 years vs. 60 years) and more likely to have a previous pulmonary embolism (86% vs. 79%). Our findings are similar to those of Taboada et al. (11). In their cohort, the median age of patients was 49 years, and a history of previ-

ous pulmonary embolism was observed in 90% of the patients. Although it may be speculated that our patients were diagnosed earlier during the course of the disease, and pulmonary hypertension was not developed at the time of surgery. Nonetheless, this is not supported by the fact that the median time from the last VTE to diagnosis was 25 months, which was similar to that observed in registry patients. On the other hand, in our previous report, the mean age of our patients was 47 years (18). Although younger CTED and CTEPH patients are seen Turkey, younger CTED patients were also seen by Taboada et al. (11) in England. We agree with the Papworth group that demographic differences are to be explained by younger patients seeking medical attention when they fail to return to their fitness status before having a pulmonary embolism.

The surgical indications for PEA have been modified over time as PEA centers get more specialized. Ever since the implementation of PEA in our center, the number of patient referrals substantially increased over the years, and we became more confident performing the procedure. All patients with CTED underwent PEA. It has been shown that CTEPH patients with increased PVR have higher mortality rates than those with PVR of $<900 \text{ dyn}\cdot\text{s}\cdot\text{cm}^{-5}$ and have a higher postoperative mortality rate if PEA cannot reduce PVR by 50% (24). On the other hand, patients who have evidence of significant thromboembolic disease but have a relatively low PVR and normal PAP may be candidates to undergo PEA to increase their exercise tolerance and eliminate dead space ventilation and prevent the development of secondary pulmonary arteriopathy and hypertension (11). van Kan et al. (16) performed cardiopulmonary exercise testing (CPET) during RHC and noninvasive CPET at 1 year following PEA in 14 patients with CTED to study hemodynamic and ventilatory responses on exercising. They concluded that patients with CTED showed abnormal pulmonary vascular response to exercise and decreased ventilatory efficiency. Responses after undergoing PEA point to the restoration of right ventricle stroke volume response and ventilatory efficiency.

It is well known that plexogenic arteriopathy describes severe pulmonary hypertensive arterial remodeling that ultimately forms plexiform lesions (25). It encompasses various forms of vascular wall remodeling, ranging from medial wall thickening to intimal occlusive and complex plexiform lesions that are specific to PAH. As only patients with symptomatic CTED in the absence of pulmonary hypertension were reviewed in this current study, no plexiform lesion was observed in the histological analysis of pulmonary artery sections.

Our study demonstrated the feasibility of performing PEA for CTED patients with significant improvement in the symptomatic status. We have also shown that surgical treatment can be safely performed in this group of patients with in-hospital mortality of 0% and 6-month survival rate of 93%. None of the patients developed pulmonary hypertension 6 months after surgery based on echocardiographic tricuspid regurgitation velocity ($<2.8 \text{ m/s}$ for all). However, surgery was not entirely risk free; complications

occurred in one-quarter of patients, which underlines the importance of patient selection for performing PEA in such a population. Our complication rate was consistent with that in other series (11, 23) and might be expected given the complexity of the surgical procedure and patients' comorbidities. Similarly, the Cambridge group (11) reported that PEA resulted in significant improvement in symptoms, exercise capacity, and quality of life in patients with CTED.

The inherent limitations of retrospective studies are valid for our analysis. As we could not analyze patients with CTED who were conservatively followed, a direct comparison between medical therapy and surgery was not possible. There was clear improvement in the 6-min walking test; however, we did not have any other objective parameter that might have quantified the benefit of surgery in these patients. A questionnaire might have provided a more objective comparison regarding differences in dyspnea/quality of life pre- and postoperatively. RHC was not performed at the sixth month because none of the patients had findings suggestive of pulmonary hypertension during the sixth-month postoperative echocardiography.

Our observations have demonstrated the feasibility of performing PEA in symptomatic patients with CTED; however, we were not able to demonstrate the superiority of PEA over medical treatment in this patient population. Although PEA leads to symptomatic improvement, its effect on the progression of small vessel vasculopathy and long-term mortality is not clear.

We agree with de Perrot and Mayer (17) that the selection of patients for PEA in the absence of pulmonary hypertension should be made after a thorough evaluation is performed and after individual discussion with patients. Indications for surgery must be made based on patients' expectations and them accepting the perioperative risk. PEA is a complex procedure that can be safely performed only in expert centers (i.e., more than 50 operations per year). This is even more important for the cohort of patients with CTED without pulmonary hypertension as their prognosis without surgical treatment is probably favorable.

Conclusion

This study demonstrates that PEA can be performed with limited risk and result in a favorable early outcome for patients with symptomatic CTED. Although PEA leads to symptomatic improvement, it is not free of complications, and its effect on long-term mortality is not clear. Given the perioperative complications and the fact that their prognosis without treatment is probably favorable, surgical treatment of CTED patients should only be performed in expert centers. The results of further prospective studies are needed to elucidate the optimal treatment strategy and optimal candidates for undergoing PEA in symptomatic patients with CTED.
